Shark Catches From Selected Fisheries Off the U.S. East Coast

July 1985

## NOAA TECHNICAL REPORTS NMFS

The major responsibilities of the National Marine Fisheries Service (NMFS) are to monitor and assess the abundance and geographic distribution of fishery resources, to understand and predict fluctuations in the quantity and distribution of these resources, and to establish levels for their optimum use. NMFS is also charged with the development and implementation of policies for managing national fishing grounds, development and enforcement of domestic fisheries regulations, surveillance of foreign fishing off United States coastal waters, and the development and enforcement of international fishery agreements and policies. NMFS also assists the fishing industry through marketing service and economic analysis programs, and mortgage in surance and vessel construction subsidies. It collects, analyzes, and publishes statistics on various phases of the industry.

The NOAA Technical Report NMFS series was established in 1983 to replace two subcategories of the Technical Reports series: "Special Scientific Report-Fisheries" and "Circular." The series contains the following types of reports: Scientific investigations that document long-term continuing programs of NMFS; intensive scientific reports on studies of restricted scope; papers on applied fishery problems; technical reports of general interest intended to aid conservation and management; reports that review in considerable detail and at a high technical level certain broad areas of research; and technical papers originating in economics studies and from management investigations. Since this is a formal series, all submitted papers receive peer review and those accepted receive professional editing before publication.

Copies of NOAA Technical Reports NMFS are available free in limited numbers to governmental agencies, both Federal and State. They are also available in exchange for other scientific and technical publications in the marine sciences. Individual copies may be obtained from: U.S. Department of Commerce, National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161.

# Analysis of Various Sources of Pelagic Shark Catches in the Northwest and Western Central Atlantic Ocean and Gulf of Mexico with Comments on Catches of Other Large Pelagics 

EMORY D. ANDERSON ${ }^{1}$

#### Abstract

Various sources of catch of pelagic sharks during 1960-81 in the Northwest and Western Central Atlantic Ocean and Gulf of Mexico, particularly within the United States Fishery Conservation Zone (FCZ), were identified and quantified. These sources included reported statistics, but principally unreported bycatch in fisheries directed towards other species. Total catch estimates during 1965-80 averaged 9,800 t (metric tons) per year and peaked at $17,300 \mathrm{t}$ in 1977 in the Atlantic FCZ and averaged $6,800 \mathrm{t}$ per year and peaked at $\mathbf{1 0 , 2 0 0} \mathrm{t}$ in 1980 in the Gulf FCZ. The major source of catch in the Atlantic FCZ was the U.S. recreational fishery, followed by the United States and Canadian swordfish longline fisheries and the Japanese tuna longline fisheries. The major sources of catch in the Gulf FCZ were the recreational fishery and the U.S. shrimp, groundfish, and snappergrouper fisheries. A comparison between long-term average catches and recent levels in both areas suggests that pelagic sharks may be excessively exploited at the present time.

## INTRODUCTION

Pelagic sharks (defined here as all sharks except dogfish) have been taken in a variety of foreign and domestic fisheries in the Northwest and Western Central Atlantic Ocean and Gulf of Mexico. Much has been as bycatch from fisheries directed towards other species, although there have been some directed fisheries for sharks. Due to the incidental nature of most shark catches, accurate statistics have invariably been lacking or only intermittently estimated.

In the late 1970's, the Gulf of Mexico Fishery Management Council and the Mid-Atlantic Fishery Management Council began developing fishery management plans (FMP's) for sharks found within the United States Fishery Conservation Zone (FCZ) in the Gulf of Mexico and Atlantic, respectively. In response to a request by the Mid-Atlantic Council for catch data to be used in developing their FMP, an attempt was made to assemble a data base comprised of reported and estimated unreported catches from various foreign and domestic fisheries. This paper presents the results of that attempt and includes 1) reported commercial catches, 2) estimates of U.S. recreational catch, 3) estimates of bycatch in the United States and Canadian longline fisheries for swordfish, 4) estimates of bycatch in the distant-water-fleet trawl fishery for squid, and 5) estimates of bycatch in the Japanese longline fishery for tuna. Information is also provided on the catch of other large pelagics in the swordfish fisheries and the squid trawl fisheries. Other possible sources of shark bycatch are indicated, and the general limitations and inadequacies of the assembled data base are discussed.

## REPORTED COMMERCIAL CATCH

## Northwest Atlantic

Reported commercial catches (defined here as the live weight equivalent of landings) of pelagic sharks from the Northwest Atlantic were obtained from ICNAF (International Commission for the Northwest Atlantic Fisheries) and NAFO (Northwest Atlantic Fisheries Organization which replaced ICNAF in 1979) Statistical Bulletins 10-31 for 1960-81, U.S. Statistical Digests (Fishery Statistics of the United States, Nos. 53-69) for 1960-76, and unpublished National Marine Fisheries Service (NMFS) data for 1977-81 (Schween and Poetzschke2; Newlin ${ }^{3}$ ).

Shark catches reported from ICNAF/NAFO Subareas 1-6 (Fig. 1) are presented in Tables 1-3. Catches reported by the Faroe Islands and Greenland were combined and listed under Denmark, although the Faroese catches accounted for most of the total. Although dogfish catches are reported separately from other sharks in ICNAF/NAFO statistics, U.S.S.R. dogfish catches prior to 1974 were reported as sharks. It was later verified that most, if not all, of the U.S.S.R. shark catches were dogfish (ICNAF Secretariat ${ }^{4}$ ); therefore, all U.S.S.R. shark catches were considered to be dogfish. In the Statistical Digests, dogfish and other sharks were combined for many years, although data since 1974 have been reported separately for dogfish (or grayfish) and unclassified sharks. Catches from states bordering on Subareas 5 and 6 (SA 5 and 6) were summed, and the ratio of unclassified to total sharks for each area each year was applied to the shark catch reported to ICNAF/NAFO to define more accurately the U.S. commercial pelagic shark catch.

The total international pelagic shark catch from the entire ICNAF/NAFO area during 1960-81 varied between 75 (1960) and $8,407 \mathrm{t}$ (metric tons) (1964) (Tables 1-3). Catches in SA 5 and 6 (comparable with the U.S. FCZ) during this period averaged about $250 \mathrm{t} / \mathrm{yr}$. The only known directed fisheries were those conducted by the Faroe Islands and Norway for porbeagle, Lamna nasus. Catches reported by other countries were assumed to have occurred incidentally in fisheries directed towards other species. During 1961-68, Norway reported shark catches as high as 7,600 $t$, but did not specify the area. The Norwegian longline fishery operated from the Middle Atlantic (SA 6) to Newfoundland (SA 3) (Aasen 1963; Casey et al. 1978; Myklevoll ${ }^{5}$ ). During 1961, 1964, and 1966, some Norwegian catches were reported from SA $3,4,5$, and 6 , although the bulk was undesignated. In the absence of any information concerning the locations (subareas) of the undesignated catches, they were assumed to be distributed in proportion to those reported by subarea. In 1961, 1964, and 1966, 44,66 , and $100 \%$, respectively, of the Norwegian catch reported by subarea came from SA 5 and 6 . The average percentage ( $70 \%$ ) was applied to the undesignated Norwegian catch in 1961-68 to estimate the amount from SA 5 and 6 , which may have been as high as $5,300 \mathrm{t}$ in 1964 . The Faroese porbeagle fishery was conducted mainly in SA 3 and 4, with small catches reported from U.S. waters (SA 5) only in 1972, 1975-77, and 1980. The only other significant reported foreign catch in SA 5 and 6 was by Japan during 1967-71. The U.S. catch in SA 5 and 6 during 1960-81 averaged 70 t/yr. The total catch in SA 5 and 6 in 1981 was 186 t , of which 180 t was reported by the United States.

## Western Central Atlantic and Gulf of Mexico

Reported commercial catches of pelagic sharks from the Western Central Atlantic and Gulf of Mexico (FAO Area 31) (Fig. 2) for 1965-81 were obtained from FAO Yearbooks of Fishery Statistics (Vols. 36, 38, 42, 44, 46, 48, 50, and 52), U.S Statistical Digests, and unpublished NMFS data.

Total international catches of pelagic sharks in Area 31 [considered to be those listed as requiem (Carcharhinidae) and various sharks in the FAO statistics] increased from $4,800 \mathrm{t}$ in 1965 to $13,700 \mathrm{t}$ in 1977, declined to $9,400 \mathrm{t}$ in 1979 , then increased sharply to $19,000 \mathrm{t}$ in 1981 (Table 4). Cuba, Mexico, and Venezuela accounted for an average of $82 \%$ of the total each year. The Cuban catch increased from 700 t in 1966 to a high of $3,800 \mathrm{t}$ in 1977, dropped to an average of $2,200 \mathrm{t}$ during 1978-80, then increased in 1981 to $3,400 \mathrm{t}$. The amount taken by Cuba in U.S. waters (Gulf of Mexico) increased steadily from about 100 t in 1972 to 1,000 t in 1976 (Table 5); no catch has been reported in U.S. waters since 1976. The extent of Cuban catches in U.S. waters prior to 1972 is unknown, although the West Florida shelf was historically a Cuban fishing area. Mexican catches in Area 31 climbed from 100 t in 1965 to $9,800 \mathrm{t}$ in 1981. Although Mexico borders the United States in the Gulf of Mexico, it is believed that most of the Mexican catch originated from Mexican waters in the vicinity of the Campeche Banks bordering the Yucatan Peninsula. Catches by Venezuela have similarly undergone a continuous increase, going from $1,700 \mathrm{t}$ in 1966 to $4,700 \mathrm{t}$ in 1981 . It is believed that most, if not all, of this has been from non-U.S. waters.

[^2]

Figure 2.-Map showing FAO Areas 21 (ICNAF/NAFO area) and 31.

Among the remaining countries reporting shark catches from Area 31 (except for the United States), only Japan, by virtue of its wide-ranging fishing operations for tuna, is believed to have taken any significant amounts of sharks from U.S. waters. The reported Japanese catch in Area 31, which declined from 800 t in 1965 to as low as 3 t in 1980, was assumed to be spatially distributed in proportion to their fishing effort reported by $5^{\circ}$ Marsden squares (see Japanese Tuna Longline Bycatch). The catch taken within the U.S. FCZ was calculated in proportion to the amount of effort reported for those $5^{\circ}$ Marsden squares located within the FCZ. Japanese catch rates for sharks were also assumed to be nearly 4 times higher in the Atlantic than in the Gulf of Mexico based on 1978-82 data (Witzell 1985). Results from this estimation procedure indicated an average of only $26 \mathrm{t} / \mathrm{yr}$ from the Atlantic FCZ and 14 t from the Gulf FCZ during 1965-81 (Table 5).
The reported U.S. catch from Area 31 has been relatively small, averaging only $1.4 \%(118 \mathrm{t} / \mathrm{yr})$ of the international total during 1965-81 (Table 4), but has exhibited an increase in recent years. The U.S. catch in 1981 was about 400 t , double the amount in 1980. The catch during 1960-81 averaged $55 \mathrm{t} / \mathrm{yr}$ in both the Atlantic and Gulf regions of Area 31 (Table 6).

## RECREATIONAL CATCH

The recreational catch of pelagic sharks in the United States has been poorly documented. Estimates of recreational catch were obtained from national surveys conducted in 1960 (Clark 1962), 1965 (Deuel and Clark 1968), and 1970 (Deuel 1973), and from regional surveys conducted in 1974-75 (Deuel ${ }^{6}$ ) and 1977-78

[^3](hereafter referred to as the 1978 survey) (Hamm and Slater 1979); since 1979, annual catch estimates have been made by the NMFS Marine Recreational Fishery Statistics Survey (MRFSS). Coverage by the regional surveys included Maine-Virginia in 1974, North Carolina-Texas in 1975, and Maine-Texas in 1977-78. Casey and Hoey (1985) reviewed the estimates of shark catch obtained from the pre-1979 surveys, while focusing primarily on the results of the 1978 survey.

Estimates of the recreational catch of sharks must be interpreted with caution. Sampling design and survey methodology have differed among the various surveys. The 1960, 1965, and 1970 national surveys were each based on a $1-\mathrm{yr}$ recall period. Response-bias errors, such as prestige-bias errors resulting from exaggeration and memory-bias errors associated with guessing, were inherent in these three surveys and likely caused overestimation of catches (Deuel and Clark 1968; Deuel 1973). The 1974-75 regional surveys employed different methods than used in the previous national surveys and were based on a 2 -mo recall period. The methodology incorporated into the MRFSS was significantly different from that employed in the earlier surveys (U.S. Department of Commerce 1980) and was intended to improve the reliability of the catch estimates. As a result of these changes, catch estimates from the earlier surveys are not directly comparable with those beginning in 1979.

The total weight of the catch was determined differently for the surveys beginning in 1979 than for those conducted earlier. In the earlier surveys, interviewed anglers provided estimates of the number and average weight of fish caught. From this information, an estimated total weight was determined. In the surveys beginning in 1979, catches were estimated in terms of numbers of fish which were 1) available for identification by the interviewer, and 2) not available for identification (butchered, discarded dead, released alive, etc.). Mean weights were obtained only from fish available for identification. In this paper, mean weights obtained from fish in the first category were also applied to fish in the second category in order to obtain an estimate of weight for the total catch.

A further complicating factor associated with the estimates of the recreational catch of sharks is that catches of dogfish were included in some surveys. Dogfish are defined as spiny dogfish, Squalus acanthias, smooth dogfish, Mustelus canis, any other species of dogfish, and other small sharks weighing $<5 \mathrm{lbs}$. Dogfish were estimated separately in the 1965, 1970, and 1979 and later surveys, but were combined with other sharks in the 1960 and 1974-75 surveys. Dogfish catches were not estimated in the 1978 survey.

The estimated recreational catch of sharks (excluding dogfish) in the Atlantic and Gulf of Mexico was 2,623 tin 1965, 9,854 tin $1970,9,759 \mathrm{t}$ in 1978, and $15,907 \mathrm{t}$ in 1980 (Table 7). The 1979 survey (U.S. Department of Commerce 1980) indicated a total Atlantic and Gulf catch of $56,270 \mathrm{t}$, grossly in excess of all other annual estimates. This estimate was considered to be extremely biased and invalid because interviewers focused their sampling efforts on shark tournaments where trip catch rates were much higher than normal (Deuel and Holliday ${ }^{7}$ ). The estimated mean weights in 1980 (Deuel and Holliday footnote 7) were quite low relative to other years even though the overall weight estimate appeared consistent with the apparently increasing trend in recreational shark catches. The Gulf catch was $43 \%$ of the total in 1965, $69 \%$ in $1970,20 \%$ in 1978 , and $38 \%$ in 1980. The catch estimated for the Gulf in both 1965 and 1970 appears to be high in comparison with that for the Atlantic and is inconsistent with the level of commercial catch in the Gulf relative to the Atlantic. In the Atlantic, the area from Maine to Virginia had a higher estimated catch each year than the North Carolina-East Florida area, averaging $70 \%$ of the east coast total in 1965, 1970, 1978, and 1980.

[^4]An attempt was made to estimate the amount of pelagic sharks included in the combined shark-dogfish estimates for 1960 and 1974-75. The proportion of sharks in the combined shark-dogfish catch in 1965 and 1970 was 84 and $87 \%$, respectively, for MaineVirginia, 53 and $76 \%$ for North Carolina-East Florida, and 40 and $96 \%$ for the Gulf of Mexico. The mean of the percentages for each area was applied to the shark-dogfish catch in 1960 and 1974-75. The results suggested an estimated catch of sharks in MaineVirginia of $9,853 \mathrm{t}$ in 1960 and $2,483 \mathrm{t}$ in 1974, in North Caro-lina-East Florida of $3,712 t$ in 1960 and $2,172 \mathrm{t}$ in 1975, and in the Gulf of Mexico of $5,116 \mathrm{t}$ in 1960 and $2,460 \mathrm{t}$ in 1975. The total for all areas for 1960 of $18,141 \mathrm{t}$ appeared unusually high compared with $9,854 \mathrm{t}$ in 1970, $9,759 \mathrm{t}$ in 1978, and $15,907 \mathrm{t}$ in 1980. Based on the general increase in recreational fishing for sharks since the mid-1960's (Casey et al. 1978), the catch in 1960 should have been no greater than in later years and more likely less. The high estimate for 1960 is likely a reflection of serious survey response-bias errors.

Estimates were made of recreational catch for years lacking angler surveys in order to obtain a continuous data series for comparison with other sources of catch. Since there were generally no unusual or sharp fluctuations in estimated catches from surveys from 1965 to 1980, values for the years lacking surveys were estimated merely by interpolation. These results are given in Table 7.

The total estimated recreational catch for all areas increased from about $2,600 \mathrm{t}$ in 1965 to a rather constant level from 1969 to 1978, during which time estimated catches averaged about 8,700 t/yr, before increasing further to about $15,900 \mathrm{t}$ in 1980. Several trends were apparent within areas, notably a general decline in the Gulf from 1970 to 1978 followed by sharp increases in 1979 and 1980, and a continuous increase in the Atlantic from 1965 to 1980.

[^5]
## SWORDFISH LONGLINE BYCATCH

Records maintained by some U.S. fishermen (Casey ${ }^{8}$ ) indicate a significant bycatch of pelagic sharks in longlining operations for swordfish, Xiphias gladius. Because sharks caught (and discarded) in the swordfish fishery have not been reported in official statistics, this component of the overall shark catch was estimated using available bycatch percentages.
Longlining for swordfish was initiated by both U.S. and Canadian fishermen in 1962 as a result of reports of the incidental capture of swordfish by Japanese and Norwegian longliners fishing for tuna and porbeagle sharks, respectively (Caddy 1976; Beckett $1971^{9}$ ). In late 1970 -early 1971, the swordfish fishery nearly ceased when U.S. Food and Drug Administration (FDA) regulations prohibited the sale of fish with a tissue content of mercury in excess of 0.5 ppm . Some swordfish continued to be caught and sold for local consumption, thus remaining technically immune from FDA regulations; some catches were reported, but apparently many operations were conducted in secrecy and significant quantities of swordfish were landed and not reported. The mercury action level was raised to 1.0 ppm in 1978 and was thought to reduce underreporting to minimal levels in 1978 and succeeding years.
U.S. longline catches of swordfish were obtained from U.S. Statistical Digests for 1962-76 and unpublished NMFS data for 1977-81 (Schween and Poetzshke footnote 2; Newlin footnote 3). The proportion of the U.S. catch taken in the U.S. FCZ in the Northwest Atlantic (SA 5 and 6) and in Canadian waters (SA 3 and 4) was ascertained from data obtained from ICNAF and NAFO Statistical Bulletins. Reported statistics during 1971-77, however, are inaccurate due to unreported catches stemming from the mercury problem.

Commercial catch data from the American Swordfish Association (ASA) for Massachusetts, Rhode Island, and Maine for 1974-77 (Booz, Allen \& Hamilton, Inc. $1980^{10}$ ) were used as a basis for estimating actual catches during 1971-77. ASA statistics for these three states combined were $173,160,221$, and $531 \%$ of the official reported catches for $1974,1975,1976$, and 1977, respectively. Reported catches from these states during 1974-77 averaged $90 \%$ of the U.S. Atlantic and Gulf of Mexico total. Assuming a similar level of underreporting everywhere during this time, the above percentages were applied to reported catches for all states in the appropriate years in order to estimate actual catches. During 1971-73, it is believed, as fishermen slowly and cautiously resumed operations following the near cessation of the fishery in early 1971, that underreporting of catches steadily increased (Casey footnote 8). A linear increase was assumed in the proportion of actual versus reported catches from $100 \%$ in 1970 (i.e., actual and reported catches were equal) to $173 \%$ in 1974. Values of 118,137 , and $155 \%$ were applied to reported catches in 1971, 1972, and 1973, respectively, in order to estimate actual catches.

Canadian catches of swordfish from SA 3-6 for 1962-81 were obtained from ICNAF and NAFO Statistical Bulletins. Longlinecaught swordfish averaged $91 \%$ of the Canadian catch during

[^6]1963-67, $98 \%$ during 1968-70, and 100\% during 1973-81 (Caddy 1976; ICNAF/NAFO Statistical Bulletins). Because the Canadian swordfish fishery "officially" ceased on 1 February 1971 (Beckett footnote 9) as a result of restrictions on mercury levels in fish, reported Canadian swordfish catches after 1970 were negligible in SA 5 and 6, but increased sharply in 1978 in SA 3 and 4 to $3,053 \mathrm{t}$ (Table 8). During 1971-77, some Canadian vessels continued to fish for swordfish which they purportedly sold and offloaded at sea to U.S. vessels. The increase in U.S. swordfish landings (both reported and actual) in the mid-1970's undoubtedly reflected some continued Canadian swordfishing activities.
The estimated United States and Canadian swordfish longline catches by area for 1962-81 (Table 8) were converted from metric tons to numbers of fish using annual mean weights of catches obtained for each area from various sources (Caddy 1976; Casey and Hoey 1985; Beckett footnote 9; Berkeley and Houde 1981; Hurley and Iles 1981 ${ }^{11}$; South Atlantic Fishery Management Council $1982^{12}$ ). The dressed weight-live weight ratio was assumed to be 0.75 . Weighted (by sample size) averages were used when areayear mean weights were available from multiple sources. When a mean weight was not available for a particular area-year, the value for the adjacent year or the mean of the preceding and succeeding years was used. Mean weights were not available for the North Carolina-East Florida area in 1964-66, but were estimated by assuming that values for those years were $16 \%$ smaller than those in the Maine-Virginia area. This was the average difference in mean weights between the two areas in 1970 and 1974-81. The same mean weights were applied to both United States and Canadian catches in a given area.
The bycatch of sharks in the United States and Canadian longline fisheries for swordfish was estimated from data obtained by Casey (footnote 8) from U.S. swordfish longline fishermen. Longline catch data were summarized by area from a total of 1) 628 sets ( 649,273 hooks) north of Cape Hatteras over a period of 10 yr, 2) 28 sets ( 29,150 hooks) between Cape Hatteras and the Florida Keys during a 4 -yr period, and 3) 198 sets ( 220,021 hooks) in the Gulf of Mexico during a 5 -yr period. The total number of sharks caught in proportion to the number of swordfish was determined for each area for all years combined. The results were rather consistent among areas, indicating a $234 \%$ bycatch of sharks north of Cape Hatteras, a $296 \%$ bycatch between Cape Hatteras and the Florida Keys, and a $213 \%$ bycatch in the Gulf of Mexico. These percentages were applied to the estimated numbers of swordfish taken in all years by longline in the four areas to obtain the estimated bycatch (in numbers) of sharks (Table 8). The estimated numbers of sharks were converted to metric tons by use of a mean shark weight of 41 kg for Nova Scotia-Newfoundland and Maine-Virginia, 42 kg for North Carolina-East Florida, and 36 kg for the Gulf of Mexico. The above values were weighted mean weights obtained by applying the mean weights for individual species (Casey and Hoey 1985) to the numbers of sharks of each species in the swordfish longline bycatch data base.
Estimated annual shark bycatch in the swordfish longline fisheries in the Nova Scotia-Newfoundland area during 1963-70 ranged between 1,300 and $5,700 \mathrm{t}$ and averaged about $3,200 \mathrm{t}$

${ }^{1}$ Assuming a shark bycatch in all years of $234 \%$ of the swordfish catch in the Nova Scotia-Newfoundland and Maine-Virginia areas, $296 \%$ in the North Carolina-East Florida area, and $213 \%$ in the West FloridaTexas area.
(Table 8). Bycatch was nonexistent during 1971-72, but averaged about $1,600 \mathrm{t}$ during 1974-77. After rising to $4,100 \mathrm{t}$ in 1978, bycatch gradually declined to about $1,300 \mathrm{t}$ in 1981 .

The estimated shark bycatch in the Maine-Virginia area was fairly steady during 1963-70, averaging $4,000 \mathrm{t} / \mathrm{yr}$ (Table 8). After dropping to only 5 t in 1971, bycatch climbed steadily to an estimated $8,700 \mathrm{t}$ in 1977 after which it declined every year to about $1,100 \mathrm{t}$ in 1981.

Prior to 1976, the only estimated shark bycatch in the North Carolina-East Florida area occurred in 1964-66 (average of 310 $\mathrm{t} / \mathrm{yr}$ ). However, beginning in 1976, estimated bycatch increased sharply from 800 to $4,100 \mathrm{t}$ in 1980-81 (Table 8).

Estimated bycatch in the West Florida-Texas area did not begin until 1969, and was relatively low (average of 170 t in 1969-70 and 1973-79) until it increased sharply to $1,400 \mathrm{t}$ in 1980-81 (Table 8).

## DISTANT-WATER-FLEET SQUID TRAWL BYCATCH

The bycatch of sharks, as well as other large pelagic species, in the distant-water-fleet (DWF) trawl fishery for squid in U.S. waters of the northwest Atlantic (ICNAF/NAFO SA 5 and 6) was estimated for 1965-81 based on NMFS foreign fisheries observer catch reports for 1978. The capture of sharks and other large pelagics in conjunction with fishing operations directed towards squid appears logical from an ecological basis. Squid are an important prey item for many shark and tuna species, swordfish, and marine mammals such as pilot whales, Globicephala melaena (Bigelow and Schroeder 1953; Scott and Tibbo 1968; Stevens 1973; Tibbetts 1977; Casey and Hoenig 1977; Dragovich 1969; Maurer 1975 ${ }^{13}$; Mercer 1974 ${ }^{14}$ ). These predators should, therefore, be susceptible to capture in trawls while feeding on the squid.

Following implementation of the Magnuson Fishery Conservation and Management Act of 1976 (P.L. 94-265) in March 1977, observers were placed aboard foreign fishing vessels to monitor and quantify the catch of all species. Vessel nationality, fishing area, number of days fished while the observer was aboard, and the total bycatch (kg) of sharks, swordfish, and other large pelagics for 1978 were obtained from the "Monthly Summary Reports on Foreign Fisheries Observer Program - Data on Bycatch and Catch Estimates" prepared by the NMFS Northeast Region, Foreign Fisheries Observer Program. Vessel days fished and the bycatch for each species were summed for each month by country. The number of vessel days on grounds each month by country was obtained from the "Monthly Summary of Fishing Activity, United States Northeast Coast," NEREIS Report 008, generated by the NMFS Northeast Regional Enforcement Information System (NEREIS).
U.S. foreign fisheries observers provided coverage aboard vessels from seven countries a total of 1,594 vessel days in 1978 (Table 9). The total number of reported days on grounds by DWF vessels in 1978 was 8,520 (Table 10). Eight countries were represented, with fishing activity greatest during NovemberDecember and January-March. With the exception of the U.S.S.R.

vessels which fished primarily for silver hake, Merluccius bilinearis, vessels from the other countries were involved in directed fisheries for long-finned, Loligo pealei, and short-finned, Illex illecebrosus, squid. Periods and areas of open fishing in 1978 are detailed in Figures 3 and 4. Gear used was primarily pelagic otter trawls.

Total bycatch of sharks, swordfish, and other large pelagics in the DWF fishery in 1978 was estimated by expanding the observed bycatch by the appropriate country-month ratios between vessel days on grounds (Table 10) and vessel days with observer coverage (Table 9). Twelve species of sharks (Table 11); swordfish; four species of tuna; ocean sunfish, Mola mola; and pilot whales were observed. The total estimated bycatch included 128 t of sharks, 71 t of swordfish, and 10 t of other large pelagics (Table 12). Carcharhinid sharks ( $44 \%$ ), hammerheads ( $23 \%$ ), and angel sharks ( $19 \%$ ) accounted for the bulk of the shark bycatch which was greatest in November ( $52 \%$ ), followed by July ( $21 \%$ ) and August ( $8 \%$ ). Swordfish bycatch was greatest in December (65\%)

The seasonality of the shark bycatch suggests differences in abundance by season and area. Less than $10 \%$ was during January-June when most fishing activity was in areas 4 and 5 and to a lesser extent in area 2 (Fig. 3). The catch during this period

was primarily lamnids (mainly basking sharks). Fishing activity during July-September was almost entirely in area 2. All areas were fished during October-December, but most of the shark bycatch during that time was in area 1 . Over $80 \%$ of the shark bycatch for the year was from areas 1 and 2 , the southernmost of the five areas with the warmest water temperatures where the abundance of sharks might be expected to be higher than in the northern, cooler areas. During the months of July, August, and November, which accounted for $81 \%$ of the shark bycatch, the catch rate of sharks averaged $41.5 \mathrm{~kg} /$ vessel day on the grounds. During the remaining 9 mo , the catch rate averaged only $4.7 \mathrm{~kg} / \mathrm{d}$, suggesting lower abundance during that time and in the areas fished than during the above 3 mo and the areas fished then. Species composition of the shark bycatch also differed during the year as lamnids were predominant during January-June (Table 12) while carcharhinids and hammerheads were predominant during July-December. These differences in species composition reflected primarily the different areas fished during those two periods.
Spanish vessels accounted for $57 \%$ of the estimated shark bycatch, with Mexican and Japanese vessels contributing 20 and $17 \%$, respectively (Table 13). U.S.S.R., Italian, and Romanian vessels took the remaining $6 \%$. Japanese vessels took $68 \%$ of the estimated swordfish bycatch

Assuming that the ratio between shark bycatch and DWF squid catch as determined in 1978 was also applicable to other years, estimates of shark bycatch ranged from 1 t in 1965 to 266 t in 1973 and averaged $134 \mathrm{t} / \mathrm{yr}$ during 1965-81 (Table 14). If fishing practices or shark abundance did not change appreciably during this period, this assumption may be valid. Because the offshore squid fisheries have been somewhat seasonal (Loligo, winterspring; Illex, summer-autumn) due to the distributional characteristics of the species, seasonal fishing patterns have not changed greatly. Although fishing by DWF vessels was restricted
by month ánd area following extended jurisdiction (Figs. 3, 4), previous patterns of fishing were not altered significantly. There have also not been any significant changes in the fishing gear used by the DWF.

Prior to extended jurisdiction in 1977, distant-water fleets fishing in what is now the U.S. FCZ caught large quantities of many species besides squid. The non-U.S. catch of all species in ICNAF SA 5 and 6 peaked at $1,021,360 \mathrm{t}$ in 1972 (ICNAF Statistical Bulletin 23), of which only $47,500 \mathrm{t}$ was squid. Given the large amount of fishing effort exerted by the DWF fishery in the 1960's and 1970's, sharks and other large pelagics may have been inadvertently captured, discarded, and not accounted for in reported catch statistics. However, evidence from the 1978 DWF fishery suggests that sharks and other large pelagics are more likely to be caught during a squid fishery than during fisheries for finfish. Comparisons of the estimated bycatch of sharks and other large pelagics as well as daily catch rates among countries in 1978 (Table 15) indicate very low values for the U.S.S.R. relative to other countries. Catch per day of large pelagics was 2.1 kg for U.S.S.R. vessels and 31.3 kg for vessels from the other five countries combined. The U.S.S.R. fishery was directed primarily towards silver hake ( $74 \%$ of total catch) and red hake, Urophycis chuss ( $11 \%$ of total catch), whereas the other countries fished mainly for squid.

## JAPANESE TUNA LONGLINE BYCATCH

Witzell (1985) reported the bycatch of sharks in the Japanese tuna longline fishery during $1978-82$ in the U.S. FCZ in the Atlantic Ocean and Gulf of Mexico based on information provided from Japanese fishing logbooks. Bycatch varied from 523 to 2,642 t in the Atlantic FCZ and from 0 to 619 t in the Gulf FCZ (Table 16).

${ }^{1}$ Includes the FCZ around Puerto Rico and the Virgin Islands.
An attempt was made to estimate the shark bycatch from the Japanese longline fishery in previous years in what is now the U.S. FCZ. The mean of the 1978-82 catch rates (for the Atlantic and Gulf separately) reported by Witzell (1985) was applied to the reported number of hooks fished yearly by the Japanese to obtain an estimate of shark bycatch during 1960-77. Effort data (number of hooks fished) reported by $5^{\circ}$ Marsden squares for the Japanese longline fishery in the entire Atlantic Ocean were obtained for 1960-77 (Zuboy and Witzell ${ }^{15}$ ). Effort from those $5^{\circ}$ Marsden squares located within the U.S. FCZ in the Atlantic (including Puerto Rico and the Virgin Islands) and Gulf was tabulated for each year (Table 16). Applying the mean 1978-82 catch rate of 37.48 t of sharks per 100,000 hooks fished for the Atlantic FCZ and $10.07 \mathrm{t} / 100,000$ hooks for the Gulf FCZ resulted in estimated shark bycatches ranging from 1 t (1961) to $2,513 \mathrm{t}$ (1971) in the Atlantic and from no bycatch in 1960-62 and 1966 to 442 t in 1977 in the Gulf (Table 16).

Estimated shark bycatch by the Japanese longline fishery in-

[^9]creased in the 1970's. Estimates for 1960-69 averaged about 500 $\mathrm{t} / \mathrm{yr}$ in the Atlantic, with the bulk attributed to effort near Puerto Rico and the Virgin Islands; estimates for 1970-79 averaged $1,113 \mathrm{t} / \mathrm{yr}$. During 1963-69, the estimated bycatch averaged 18 $\mathrm{t} / \mathrm{yr}$ in the Gulf; estimates for 1970-79 averaged $190 \mathrm{t} / \mathrm{yr}$. The increase in estimated bycatch in the 1970's occurred as a result of an increase in Japanese effort in the U.S. FCZ. During 1960-69, about $10 \%$ of the total Japanese effort each year in FAO Areas 21 and 31 (Fig. 2) was in U.S. waters, compared with $40 \%$ during 1970-77.

## OTHER SOURCES OF BYCATCH

Additional bycatch of pelagic sharks occurs in fisheries other than those described above; however, data on which to base such estimates, at least in the Atlantic, are not available. In the Gulf of Mexico, there apparently is a significant bycatch of sharks in the U.S. trawl fisheries for shrimp and groundfish. The total shark bycatch by U.S. shrimp vessels in the Gulf FCZ has been estimated to exceed 5 million $\mathrm{lb}(2,270 \mathrm{t})$ annually, and an additional annual bycatch of about $250,000 \mathrm{lb}(113 \mathrm{t}$ ) has been estimated to occur in the Gulf from the snapper-grouper fishery and other miscellaneous sources (Gulf of Mexico Fishery Management Council see Table 5, footnote 2).

## DISCUSSION

Reported commercial catches of pelagic sharks in the Atlantic and Gulf FCZ, as well as estimates of recreational catches and bycatches from several sources, have been presented in this paper. In order to properly evaluate and interpret these results, it must be understood that these estimates are generally imprecise and require the broad application of various assumptions. Assumptions concerning mean weights, extrapolation and interpolation of catches and catch rates, and the like all represent sources of error. Particular errors associated with the recreational catch estimates were mentioned earlier. In addition, all sharks caught as bycatch in longline fisheries for swordfish and tuna and released are assumed to be dead or die thereafter. This assumption may not be valid, but data on the survival of released sharks was not available. Therefore, the estimates presented must not be treated as accurate measures of catch, but as approximations. They do, however, represent the first attempt to identify and quantify the major sources of shark catch in U.S. waters of the Atlantic and Gulf of Mexico.
A further limitation of the results is the inability to provide catch estimates by species. For some components of the overall catch in particular years and areas, species composition may be approximately known. Some of this information is available from other sources (e.g., Casey and Hoey 1985; Gulf of Mexico Fishery Management Council, see Table 5, footnote 2; Casey unpubl. data). For example, a high percentage of both the recreational catch and the bycatch in the swordfish longline fishery in the northwest Atlantic consists of blue sharks, Prionace glauca. The Norwegian and Faroese longline fisheries of the 1960's were for porbeagles. Bycatch in the swordfish longline fishery in the Gulf of Mexico includes a high proportion of sharks of the genus Carcharhinus.
In spite of the uncertainty of all the various estimates of catch presented, it is useful to examine totals and trends within each area (Atlantic FCZ and Gulf FCZ). Because of the incompleteness of the estimates (particularly the recreational component), total catches can only be compared during 1965-80 (Table 17). others), 1960-81.

[^10]Estimated total shark catches in the Atlantic FCZ during $1965-80$ averaged about $9,800 \mathrm{t} / \mathrm{yr}$ (range $=5,500-17,300 \mathrm{t}$ ) (Table 17). Catches increased sharply in the early 1960's to about $14,300 \mathrm{t}$ in 1964 (assuming a recreational catch of about $1,500 \mathrm{t}$ as in 1965). This increase was due to the start of the Norwegian porbeagle fishery in 1961 and the advent of longlining for swordfish by the United States and Canada in 1962. The decrease to $6,200 \mathrm{t}$ in 1967 was due in large part to the virtual collapse of the porbeagle fishery. Norwegian catch per unit effort (CPUE) decreased from 9.1 sharks 100 hooks in 1961 to 2.9 in 1964 (Myklevoll footnote 5). The catch rate presumably decreased further as the Norwegian catch in the ICNAF area declined from $8,060 \mathrm{t}$ in 1964 to only 270 t in 1968 (Table 3). The Faroese porbeagle fishery similary experienced a drastic decline in CPUE after the mid-1960's and also a proportionate decrease in the average size of fish caught (Hoydal ${ }^{16}$ ). The total catch was relatively stable during 1966-75 and ranged only from 5,500 to 8,900 $\mathrm{t} / \mathrm{yr}$ (average $=7,000 \mathrm{t}$ ). The total catch began increasing in the mid-1970's due to improving recreational catches and bycatches in the expanding U.S. swordfish fishery, reached a peak of 17,300 t in 1977, and averaged $16,200 \mathrm{t}$ annually during 1977-80.

Shark catches in the Atlantic FCZ during 1965-80 attributed to U.S. fishing activity exceeded those by other countries in all years except 1965-66 and 1968-70 (Table 17). U.S. catches ranged between 2,700 (1966) and $16,700 \mathrm{t}$ (1977) and averaged about $3,1.00 \mathrm{t}$ annually during 1965-71 ( $42 \%$ of the total). Catches then increased until 1977, when they leveled off averaging $14,600 \mathrm{t} / \mathrm{yr}$ (1977-80) and $90 \%$ of the total. The major source of U.S. catch was the recreational fishery, followed by the swordfish longline fishery. The principal source of catch by other countries was the

[^11]Norwegian porbeagle fishery in the early 1960 's, followed by the Canadian swordfish longline fishery during 1963-70, and the Japanese tuna longline fishery throughout the entire period.
Estimated shark catches in the Gulf of Mexico FCZ averaged about $6,800 \mathrm{t}$ yearly during 1965-80 (range $=3,500-10,200 \mathrm{t}$ ) (Table 17). A constant annual bycatch of $2,383 \mathrm{t}$ was assumed from the U.S. shrimp, groundfish, and snapper-grouper fisheries. Catches reached an apparent peak in the Gulf in 1970 at about $9,500 \mathrm{t}$ due to increased recreational catches, followed by a gradual decrease to $4,600 \mathrm{t}$ in 1978. Catches then again increased sharply to a high of $10,200 \mathrm{t}$ in 1980. U.S. catches during 1965-80 averaged about $6,400 \mathrm{t} / \mathrm{yr}$ (about $95 \%$ of the total). The major source of U.S. catch was the recreational fishery. As indicated earlier, the recreational catch estimates for the Gulf in 1965 and particularly in 1970 appear to be excessive relative to the Atlantic and are inconsistent with commercial catch trends in the two areas.
It is possible that some of the shark bycatch estimated in this paper and assumed to be nonreported could have been landed and included in reported commercial statistics resulting in some double counting. In the case of U.S. fisheries, the reported commercial catch of sharks has been so small relative to the estimated recreational catch and swordfish bycatch that any double counting would not significantly alter the total estimate. The estimated amounts taken by the DWF squid fishery (average of $200 \mathrm{t} / \mathrm{yr}$ during 1972-81) would also not affect the final results. The reported Japanese shark catch does not represent the total amount actually taken in their tuna longline fishery. The amounts estimated as bycatch in their longline fishery (Table 16) generally exceed their reported catches in FAO Area 31 (Table 4), especially during 1970-81. Only in several of the years in the 1960's did the estimated Japanese longline bycatch correspond well with the catch reported to FAO for Area 31. The Japanese shark catches reported
in the ICNAF/NAFO area are not indicated as being taken by longline gear. Any double counting of Japanese catches will not significantly affect the total estimated catch.

No attempt was made in this paper to estimate maximum sustainable yield (MSY) based on an analysis of catch and effort data. Catch data are uncertain, and the inclusion of multiple species in the catch estimates generates an unknown response of this mixture to fishing mortality. There is a lack of fishing effort data for sharks, although Otto et al. ( $1977^{17}$ ) used Japanese longline effort data to calculate an MSY estimate for sharks in the western North Atlantic. The Schaefer $(1954,1957)$ surplus-yield model, which employs catch and effort data to estimate MSY, assumes, among other things, 1) an immediate increase in population size (through recruitment) following a population decrease, and 2 ) the rate of population increase is independent of the population's age composition. Neither of these assumptions is valid for sharks (Holden 1974, 1977). Sharks have a very low reproductive potential compared with teleost fishes, a delayed and slower recovery from exploitation, and exhibit a close relationship between stock and recruitment (i.e., reproductive potential is greatest at virgin biomass levels and decreases as the population decreases). Shark populations would be very vulnerable to fishing, and, therefore, due caution and consideration must be exercised in developing a fishery for sharks.

One approach to estimate long-term potential yield is to examine historical catch levels. As mentioned above, the 1965-80 average level of estimated catch in the U.S. FCZ in the Atlantic was about $9,800 \mathrm{t}$, and about $6,800 \mathrm{t}$ in the Gulf FCZ. These estimates would be first-order approximations of long-term yield, although the average level for the Gulf is probably too high as a result of apparent overestimates in recreational catch in some years.

The 1980 estimates of shark catch in the FCZ were about $17,100 \mathrm{t}$ in the Atlantic and $10,200 \mathrm{t}$ in the Gulf. These estimates were $7,300 \mathrm{t}$ above the 1965-80 average in the Atlantic and 3,400 $t$ above the 1965-80 average in the Gulf. Sharks in both the Atlantic and the Gulf may be excessively exploited at the present time if the 1965-80 average catch levels represent valid estimates of MSY. However, since catch rates and trends for individual species are lacking to indicate any changes in abundance, this cannot be confirmed. The fact that sharks are very vulnerable to fishing has been demonstrated in various situations such as the Norwegian (Myklevoll footnote 5) and Faroese (Hoydal footnote 16) porbeagle fisheries in the northwest Atlantic, the California soupfin shark fishery (Ripley 1946), the Scottish-Norwegian spiny dogfish fishery (Holden 1968), and the Australian school shark fishery (Olsen 1959). The increasing trend in estimated catches in the Atlantic FCZ since the early 1970's and in the Gulf FCZ since the late 1970's reflects increased fishing pressure, which, if continued, may result in a decline in the overall abundance of pelagic sharks. Further attempts to evaluate the general abundance of sharks will require information on catch rates or other indices of abundance over a period of years.

# Estimated Catches of Large Sharks by U.S. Recreational Fishermen in the Atlantic and Gulf of Mexico ${ }^{1}$ 

JOHN G. CASEY and JOHN J. HOEY ${ }^{2}$

## INTRODUCTION

Several species of large Atlantic sharks are an important resource to the U.S. recreational fishery (Table 1). Sharks have been fished commercially in the past (Springer 1952) and, despite their present low value, the stocks are considered potentially valuable to U.S. commercial interests. World landings of elasmobranch fishes (sharks, skates, rays) in 1981 were $600,607 \mathrm{t}$ (metric tons), or about one-fourth of the world's combined landings of tuna, swordfish, and billfishes (Thompson 1983). In the face of increasing world demand for food and byproducts from the sea, an increase in the harvest of sharks in the U.S. Fishery Conservation Zone is assured.

In the Atlantic, new fisheries for sharks are likely to develop along several lines as the demand for recreational opportunities, and the value of flesh, fins, or byproducts increases. Judging from the recent growth of the recreational fishery for sharks off the U.S. northeast coast and the continuing interest of fishermen in sharks as "big game fish," recreational fishing for large sharks will continue to increase along the entire Atlantic coast. Currently a high percentage of the sharks caught by recreational fishermen are released or discarded with the remainder being mounted for trophies or brought home for food. Some species, such as the shortfin mako, are highly prized for home consumption and often sold to processors to defray the costs of offshore fishing trips. Should the commercial value of sharks increase, some of the vessels now regarded as sport boats would move into commercial operations and thereby increase fishing mortality on the more common or desirable species including blue and mako sharks. In addition, existing United States and Canadian longline fisheries for swordfish, and foreign longline fisheries for tunas, could be quite easily directed to sharks. Longline catch data for swordfish and tuna from United States and foreign vessels indicate that the bycatches of sharks can often exceed (sometimes doubling or tripling) the catches of the target species (Casey and Hoenig 1977). Considering that these fisheries attempt to avoid sharks, it follows that the longline catch of sharks could be increased dramatically (if temporarily) with little or no additional investment. Intensive commercial fisheries for sharks are likely to reduce the abundance of some species in only a few years. In 1960 a longline fishery for porbeagle sharks, Lamna nasus, was established in the western North Atlantic (primarily by the Norwegians). From 1961 to

[^13]1964 annual catches increased from 1,800 to $9,300 \mathrm{t}$ then declined sharply to about 200 t (Casey et al. 1978). Growth to maturity in the porbeagle shark takes about 6 to 9 yr (Aasen 1961) and normally four young are produced. The slow growth rate and low reproductive potential, characteristic of many elasmobranchs, may explain the above decline in porbeagle catches. The susceptibility of other shark species to intensive fishing is discussed by Holden (1973, 1974, 1977) and Ripley (1946).

The probability of increased fishing mortality on sharks has given rise to concern among recreational fishermen and some members of fishery management councils. The Preliminary Management Plan (PMP) for sharks now in place for the U.S. FCZ in the Atlantic allows for a total allocation of $1,150 \mathrm{t}$ of sharks for foreign fisheries. ${ }^{3}$ Only the Faroe Islanders have requested and received an allocation of sharks under the PMP. Since 1978 they have had an allocation of 500 t of porbeagle sharks with a 100 t bycatch allocation of finfish. They have never completely utilized their allocation, catching only 5 t in 1980 and approximately 100 t in 1982. ${ }^{4}$ In 1983 and 1984 the Faroe Islanders did not fish in the U.S. FCZ.

[^14]Table 1.-List of common and scientific names used in this report.

| Blue shark | Prionace glauca |
| :--- | :--- |
| Bull shark | Carcharhinus leucas |
| Dusky shark | Carcharhinus obscurus |
| Lemon shark | Negaprion brevirostris |
| Nurse shark | Ginglymostoma cirratum |
| Oceanic whitetip shark | Carcharhinus longimanus |
| Porbeagle | Lamna nasus |
| Sandbar (brown) shark | Carcharhinus plumbeus |
| Shortfin mako | Isurus oxyrinchus |
| Silky shark | Carcharhinus falciformis |
| Tiger shark | Galeocerdo cuvieri |
| White shark | Carcharodon carcharias |
| Blacktip shark | Carcharhinus sp. |
| Hammerhead shark | Sphyrna sp. |
| Bigeye thresher | Alopias superciliosus |
| Swordfish | Xiphias gladius |
|  |  |

The purpose of this report is to provide estimates of the total number and weight of the large sharks caught by recreational fishermen along the Atlantic coast of the United States, including the Gulf of Mexico. The estimates were calculated by applying weight and species composition data on sharks to results of a 1978 marine recreational fishing survey by Hamm and Slater (1979). Previous surveys of marine recreational fishing which included sharks were conducted in 1960, 1965, 1970, and 1974-75. These earlier surveys were based on broad sampling of the general fishing public in order to estimate the total marine recreational catch. The sampling design focused on catches of smaller abundant gamefish species (flounders, mackerel, bluefish, etc.). Reports of large tuna, swordfish, and sharks were considered rare events in the sampling scheme. ${ }^{5}$ In addition, these surveys did not distinguish between the different species of large sharks and were inconsistent by listing dogfishes (Squalus sp. and Mustelus sp.) separately in some years, and including them under "all sharks" in others (Table 2). The Hamm and Slater (1979) survey differed in that it was designed to estimate only the catch of billfish and large sharks and was based on sampling from registrations of large offshore sport boats ( $18-65 \mathrm{ft}$ ). Because the survey estimated the catches from a specific component of the shark fishery, and because it provided information on species composition, we considered the results to be the best available data for calculating the total weight of large sharks caught by recreational fishermen along the U.S. east coast including the Gulf of Mexico.

## MATERIALS AND METHODS

The Hamm and Slater (1979) survey provided species composition information and estimated numbers of large sharks caught by sportsmen for five regions in the western North Atlantic. For our analysis we used three regions by combining the Hamm and Slater data from North Carolina to Florida; Florida East Coast and Keys; Puerto Rico and U.S. Virgin Islands; and "Other Waters" into a single region which we designated Atlantic-South of Virginia. The other two regions were Atlantic-North of Virginia and Gulf of Mexico. Estimates of the total weight of the recreational catch of large sharks in each region were calculated by applying average weight data from biological sampling of tournament and research vessel shark catches (Apex Predator Task/NMFS/NEFC/Narr. RI), (Table 3), to the species composition information from the Hamm and Slater survey. Two methods were used and compared to obtain weight estimates. The first estimate was obtained by expanding the species composition information using all areas combined. The average weight data in Table 3 were multiplied by the number of each species reported for all regions (Table 4d). Data for southern sharks were limited because most of the biological sampling occurred north of Cape Hatteras, NC, so it was not possible to assign an average weight to every species reported. The estimate of the total weight of sharks caught was calculated by establishing a proportion which related the number and total weight of dominant shark species to the number and total weight of all sharks:

No. of dominant shark species Tot. wt. of dominant shark species
No. of all sharks caught $\cdot$ Tot. wt. of all sharks caught

[^15]In a second estimate, we calculated the weight of sharks caught in each region separately (Table 4a, b, c). As in the preceeding calculations, we applied average weight for each species to the dominant species reported in each region. The weight values for the regional catch were estimated by utilizing the described proportional relationship between the dominant species with assigned weights and the total catch. By summing the regional weight estimates, a second estimate of the total weight for all regions was obtained.

## RESULTS

Average fork lengths (cm) and weights (lb) for eight species of Atlantic sharks are presented in Table 3. These values were calculated from sharks examined at sport fishing tournaments in New Jersey and New York, and on research cruises in the FCZ primarily between Cape Hatteras, NC, and Georges Bank.

Species composition data from the Hamm and Slater (1979) survey are presented in Table 5 together with information from the NMFS Cooperative Shark Tagging Program and longline records representing 41,353 sharks of 32 species. Based on these sources of species composition data the sharks listed in Table 5 include the most common species taken by recreational fishermen.

Hamm and Slater (1979) reported the following numbers of sharks caught within the U.S. FCZ in the Atlantic and Gulf of Mexico:

| Atlantic—North of Virginia | 124,226 |
| :--- | ---: |
| Atlantic—South of Virginia | 59,788 |
| Gulf of Mexico | 46,405 |
| Total catch | 230,419 |

The calculated total weights of sharks caught in each region are:

| Atlantic—North of Virginia | $5,502 \mathrm{t}(12,129,450 \mathrm{lb})$ |
| :--- | ---: |
| Atlantic—South of Virginia | $2,780 \mathrm{t}(6,127,885 \mathrm{lb})$ |
| Gulf of Mexico | $1,973 \mathrm{t}(4,350,304 \mathrm{lb})$ |
| Total | $10,255 \mathrm{t}(22,607,639 \mathrm{lb})$ |

The calculated weight of sharks caught in all regions combined is $10,277 \mathrm{t}(22,656,576 \mathrm{lb})$ (Table 4). This estimate is very close to the first estimate of $10,255 \mathrm{t}(22,607,639 \mathrm{lb})$ obtained by expanding the species composition information from each area.

## DISCUSSION

Estimates of the U.S. recreational catch of sharks from several national surveys show wide variation in the numbers and average weights for the different years (Table 2). For all areas combined, the average weights from the national surveys ranged from 13.8 to 98.5 lb with much lower values in the early years compared with the most recent survey (Hamm and Slater 1979). The lower average weights for the 1960 and 1974-75 surveys may, in part, be due to including dogfish and sharks as a single category in those years. However, that would not explain why the average weights for the 1965 and 1970 surveys also appear low when dogfish were recorded separately. Rather than speculate on the sources of variation among the early national surveys where detailed information is lacking, we considered it more useful to base our analysis on the 1978 survey (Hamm and Slater 1979). Results of that survey provided data on the numbers of sharks caught that could be com-

${ }^{4}$ Blacktip average length $=129 \mathrm{~cm}$ based on 73 specimens (Dodrill 1977). We assume that the blacktip and sandbar have a similar length-weight relationship which is 55 lb for a 129 cm blacktip.
${ }^{5}$ Bull shark average length $=160 \mathrm{~cm}$ based on 14 specimens (Dodrill 1977). We assume that the dusky and bull have a similar length-weight relationship which is 103 lb for a 160 cm bull shark.
${ }^{6}$ This estimate appears high based on our knowledge of this species. This appears to be an example of a "glamorous" species being overestimated.
pared and integrated with the weight data on sharks we measured at tournaments and on research vessels. In addition, the 1978 results were more in line with our observations of the recreational fishery for large sharks during the past 15 yr in terms of the species composition, sizes of vessels participating, and average daily catch rates. Nevertheless, the 1978 survey introduced sources of bias that should be noted. The survey was designed primarily to evaluate the sport catch of billfishes and was limited to offshore fishing from larger sport boats. Consequently, the incidental recreational catch of sharks from shore and small boats was not included. ${ }^{6}$ Inshore landings, particularly of juvenile and smaller sharks, are not reported and are considerable in some areas.

Offshore fishermen tend to use heavier gear which selects for larger sharks. Consequently, the average weight of sharks in the 1978 survey (and our data base) is higher than if all segments of the recreational fishery were represented. Another possible source of error arises from the fact that many fishermen tend to report only more distinctive species of sharks (e.g., hammerhead, tiger, mako, etc.). In addition, the most desirable species are more likely remembered and their relative abundance overestimated. Finally, many sharks are released in the recreational fishery. Although this is a source of mortality, some survive and are caught more than once. From tagging studies of 45,000 sharks, the overall recapture rate is $3.2 \%$ (J. G. Casey, unpubl. data). The release of large numbers of sharks would produce higher than actual estimates of the population. Despite these shortcomings, the 1978 survey presents the best available estimate of the current recreational catch of large sharks in terms of the numbers caught and the species composition of the catch.

By applying our average weight data from over 5,000 sharks of eight species and distribution information from 45,000 tagged sharks, we estimate the recreational catch of large sharks from the Atlantic in 1978 was $10,277 \mathrm{t}$ ( 22.6 million lb). This estimate is based primarily on sharks caught offshore from sport fishing boats and does not include dogfishes, sharks caught from shore, or small sharks caught incidentally to other gamefish species. Consequently , we believe the estimated catch of 22.6 million lb is conservative. Moreover, fishing effort for sharks has continued to increase in recent years and likely will continue to do so particularly along the southeast coast and in the Gulf of Mexico.

## ACKNOWLEDGMENTS

We thank Mark Holiday for providing catch data and Kenneth Sherman for helpful comments on the manuscript. Nancy Kohler and Patricia Hadfield provided valuable editorial assistance.

# The Incidental Capture of Sharks in the Atlantic United States Fishery Conservation Zone Reported by the Japanese Tuna Longline Fleet 

W. N. WITZELL ${ }^{1}$

#### Abstract

An analysis of pelagic sharks captured incidentally by the Japanese tuna longline fleet was performed for the years 1978 through 1982. The overall CPUE and percentage of sharks reportedly killed in the Gulf of Mexico and the Atlantic varied considerably, $0.1335(14.7 \%)$ and 0.5988 ( $\mathbf{7 . 2 \%}$ ), respectively. These differences are probably due to the fact that the fishery is dynamic, and changes in gear and methods frequently occur, depending on the geographic location and the target species.

## INTRODUCTION

The U.S. offshore fisheries are managed inside a 200 nmi Fishery Conservation Zone (FCZ) as promulgated by the Fishery Conservation and Management Act (FCMA) of 1976. All foreign vessels wanting to fish within the FCZ must obtain a permit, maintain accurate fishing records showing amount and location of catch and effort, release all nontarget species (dead or alive), and allow U.S. observers on board vessels. The incidental capture of large pelagic fishes, particularly sharks, by commercial fishing fleets in U.S. waters has been inadequately addressed. Several commercial fisheries incidentally capture pelagic sharks in the U.S. waters, but published accounts are limited (Lopez et al. 1979). The quantification of the incidental capture rate of sharks by each fishery is necessary when formulating conservation and management strategies as mandated by the FCMA. This paper analyzes the incidental capture of sharks by the Japanese tuna longline fleet inside the U.S. Atlantic FCZ for the years 1978 through 1982.

The Japanese tuna longline fishery is fished from vessels ranging in length from 50 to 70 m . A mainline, 100 to 135 km long, is suspended horizontally from the surface by a series of floats. Suspended vertically from the mainline are a series of branch lines, 15 to 25 m long, each line terminating with a hook baited with mackerel, saury, or squid. The longline is set between 0000 and 0800 from a moving vessel and hauled back from 1200 to 0000 . The fishery is dynamic, and changes in gear and methods frequently occur, depending on the geographic location and the target species. The Japanese tuna longline fishery in the U.S. Gulf of Mexico has been described in detail by Lopez et al. (1979).

## MATERIALS AND METHODS

Three available computerized data sources are pertinent to the longline fishery: 1) the U.S. observer file, used here to describe the fishery; 2) the actual numbers of incidentally caught fish and effort reported quarterly by the Japanese fishing logbooks; and 3) the average weights of sharks captured by the National Marine Fisheries Service exploratory longline surveys. These three data

[^17]bases are maintained by the National Marine Fisheries Service, Southeast Fisheries Center (SEFC), Miami, FL. The fishing materials and methods used by the Japanese longline fleet are described by Lopez et al. (1979), and by Bullis (1955) and Captiva (1955) for the SEFC exploratory longline surveys. The observed incidental catch by the Japanese longline fleet and the exploratory incidental catch data were collected opportunistically during tuna and swordfish surveys, and it is felt that comprehensive statistical analyses of these data are inappropriate.

For the purpose of this report, the U.S. Atlantic Ocean FCZ is divided into two subareas: Atlantic (off the eastern U.S. coast) and Gulf of Mexico. The catch-per-unit-effort (CPUE) is the number of sharks caught per 100 hooks fished.

## RESULTS AND DISCUSSION

The overall CPUE of sharks in the Gulf of Mexico and Atlantic varies considerably, 0.1335 and 0.5988 , respectively (Table 1). This is probably due to the large numbers of blue sharks, Prionace glauca, normally found in the Cape Hatteras area (Casey 1976), where the Japanese longliners have concentrated their fishing effort for tuna over the years. There is no readily discernable seasonal pattern of shark CPUE in either the Gulf or the Atlantic and annual variations of shark CPUE are also difficult to interpret (Table 2). The variations of CPUE-geographical, seasonal, and annual-possibly reflect the dynamic nature of the fishery. The vessel captains change fishing strategies temporally, spatially, or both, as each situation demands in order to maintain high catch levels of target fish and to reduce shark catch. Longline fisheries targeting sharks have a higher CPUE. For instance, the CPUE for blue shark longlining between Cape Hatteras and Cape Cod, MA, was 6.3 (Casey 1976), and Bullis (1976) reported maximum CPUE's ranging from 4.1 to 12.2 in the U.S. southeast Atlantic area.

The incidentally captured sharks are combined into a single species group because the observers were often unable to accurately identify sharks in the water from a moving vessel. However, the mean weights of sharks captured during exploratory surveys in the South Atlantic area ( 62.4 kg ) and Gulf of Mexico $(80.4 \mathrm{~kg})$ are broken down by species in Table 3. The mean weight of the Atlantic sharks is considered high for this analysis

because the exploratory surveys were primarily conducted south of Cape Hatteras, NC, and therefore do not include the smaller blue shark which is most frequently captured in the northern Atlantic by the Japanese fleet. The mean weights of sharks caught during exploratory surveys are used to calculate total shark weights. The total weights of the sharks (Table 2) caught in the Gulf of Mexico, $1,209.4 \mathrm{t}$, and Atlantic, $7,312.7 \mathrm{t}$, reflect the differences in CPUE and total fishing effort between these two areas. However, the percentage of sharks killed, reported by U.S. observers on Japanese tuna vessels in the Gulf and Atlantic, is low, 14.7 and $7.2 \%$, respectively.
