Abstract.—Recent papers have provided new insights into the problem of estimating von Bertalanffy growth parameters from tag-recapture data. In particular, the inconsistency and bias of Fabens’ (1965) estimates appear to have been addressed by James (1991). Using simulation, we examine the pattern of bias associated with different error assumptions for Fabens’ estimates, weighted Fabens’ estimates proposed by James, and a robust method also proposed by James. Our results corroborate James’ finding that his robust estimates can be significantly less biased than other methods. We then apply these estimators to tag-recapture data obtained for sablefish *Anoplopoma fimbria* found in the Gulf of Alaska and off the U.S. west coast, and Pacific cod *Gadus macrocephalus* found in the eastern Bering Sea. These species are difficult to directly age, so tag-recapture data provide welcomed independent estimates of growth parameters and an indirect method of validating age-determination criteria. The von Bertalanffy parameter estimates using tag-recapture data and James’ method were most similar to estimates calculated directly from length-at-age data.

In its most common form, the von Bertalanffy growth curve has three parameters \((L_\infty, K, t_0)\). Conventional interpretation of these parameters is that \(L_\infty\) is asymptotic size, \(K\) describes the growth rate, and \(t_0\) describes the age at length-0. Fabens (1965) was apparently the first to show how least-squares could be used to estimate two of these parameters \((L_\infty, K)\) from tag-recapture data. If at least one additional value of length-at-age was known, then \(t_0\) could be estimated, and hence all values of length-at-age could be estimated directly from recapture data without recourse to direct ages from individual specimens. Besides providing growth-curve estimates, such a procedure would seem to provide an indirect validation of ageing criteria, since estimated growth parameters from length-at-age data and tag-recapture data could be compared.

However, comparisons of growth curves estimated using Fabens’ method and ordinary length-at-age data seemed to provide evidence that Fabens’ method provided biased parameter estimates. Following the suggestion of Chapman (1961) and others, Sainsbury (1980) showed how individual variability (i.e., the possibility that each fish has different values of \((L_\infty, K)\), could lead to bias in population parameter estimates. Francis (1988a) argued from a sampling point of view that von Bertalanffy parameters calculated from length-at-age and tag-recapture data could be different. He also argued that average growth parameters for individual fish may not describe the population growth curve (Francis 1988b). Maller & deBoer (1988) showed mathematically and with simulation that Fabens’ estimates, and related estimates of Kirkwood & Somers (1984), could be inconsistent. Kirkwood (1983) suggested combining length-at-age and tag-recapture data into a single likelihood model, but did not address the problem of bias caused by the interpretation of tag-recapture data.

A recent paper by James (1991) suggests that bias in Fabens’ estimates could arise from bias in the estimating functions. James shows how weighted least-squares can be used to derive improved estimates for Fabens’ method under the usual “observational error” assumption. James also gives distribution-free estimates for a more general model in which, in addition to the usual observational error, \(L_\infty\) itself is allowed to vary among individual fish. Although James’ estimates appear to be consistent and less biased than the least-squares estimates, they also appear to be less efficient, usually...
having larger standard errors. Nevertheless, James’ method provides us with more robust parameter estimates.

This paper illustrates how critical is statistical methodology to the estimation of growth parameters from tag-recapture data. We show, by simulation and through analysis of actual data, that different estimation methods can easily lead to very different parameter estimates. With the help of simulation, we feel that realistic choices can be made among these estimators. For the actual datasets chosen for this paper, we are able to compare growth-curve parameter estimates from tag-recapture data with parameter estimates calculated from length-at-age data, using ages estimated from directly counting annuli. This provides another criterion for choosing among estimators.

Methods

We apply estimators considered by James (1991). The “unweighted Fabens” estimates (Fabens 1965) is the widely used historical method. What we call the “weighted Fabens” estimates, and James’ estimates, were derived by James (1991). The weighted Fabens’ method weights the residuals by an inverse variance estimate and appears to work well for the observational error model. James’ estimators appear to be less prone to bias than the unweighted Fabens’ estimators, and more robust to the presence of variability in \( L_\text{a} \) than the weighted Fabens’ estimators. A more theoretical description of these estimators can be found in James (1991).

First we present a simulation study that corroborates the main findings of James (1991). Our study is more systematic than that of James (1991), using three estimation methods and error structures and calculating mean square error. Our simulation is based on parameters estimated for a marine teleost, Pacific whiting *Merluccius productus*, while James’ simulations dealt with two shellfish species. Nevertheless, these simulations should be considered an addendum to James’ original work.

Using notation similar to James (1991), consider a population having von Bertalanffy parameters \((L_0, K_0)\) which we wish to estimate. \( L_0 \) refers to the average value of \( L_\text{a} \) in the population, where \( L_\text{a} \) might vary among individual fish. We assume \( K=K_0 \) does not vary among fish. Also, recall that \( t_0 \) cannot be estimated from tag-recapture data alone. To determine \( t_0 \) we need the average length of at least one age-group which can be supplied by direct age data (i.e., ages obtained from directly counting annuli), or the modal length-frequency of a dominant year-class of known age.

Suppose we observe the size at release \((y_{1i})\) and recapture \((y_{2i})\) of \( i=1,...,n \) fish, and the ages at release and recapture are \((t_{1i}, t_{2i}+d)\). Suppose also that independent normally-distributed errors \((\varepsilon_{1i}, \varepsilon_{2i}, \varepsilon_{3i})\) enter into these observations in three possible ways:

\[
\begin{align*}
y_{1i} &= (L_0 + \varepsilon_{3i})[1.0 - \exp(-K_0 t_{1i})] + \varepsilon_{1i} \\
y_{2i} &= (L_0 + \varepsilon_{3i})[1.0 - \exp(-K_0 (t_{2i} + d))] + \varepsilon_{2i}.
\end{align*}
\]

We refer to \( \varepsilon_{1i} \) and \( \varepsilon_{2i} \) as “observational errors” and \( \varepsilon_{3i} \) as “variability in \( L_\text{a} \)”.

The three estimators of \((L_0, K_0)\) considered in this paper are all based on the “residuals”:

\[
\eta_i = y_{2i} - y_{1i} - (L_0 - y_{1i})[1.0 - \exp(-K_0 d_i)].
\]

These estimators are:

1. Unweighted Fabens, estimated by minimizing \( \sum \eta_i^2 \).
2. Weighted Fabens, estimated by minimizing \( \sum [\eta_i^2/(1.0+\exp(-2K_0 d_i))] \).
3. James, estimated by solving the simultaneous equations \( \eta_i=0 \) and \( \Sigma \eta_i=0 \).

Unweighted and weighted Fabens’ estimates, and their standard errors, were calculated using nonlinear least-squares methods. Define \( g_1=\sum \eta_i \) and \( g_2=\Sigma \eta_i \). James’ estimates were calculated as suggested by James (1991) by solving for “\( L_0 \) in terms of \( K_0 \) from \( g_1 \) followed by substitution into \( g_2 \)” and then applying the bisection method to estimate \( K_0 \) (see Press et al. 1986). This method appeared computationally robust and suitable for simulation studies. The variance estimates of these parameter estimates were calculated according to James (1991):

\[
\text{cov}(\hat{L_0}, \hat{K}) = G^{-1}D(G')^{-1},
\]

where

\[
G = \begin{pmatrix}
g_1 \frac{\partial g_1}{\partial L_0} & g_1 \frac{\partial g_1}{\partial K_0} \\
g_2 \frac{\partial g_2}{\partial L_0} & g_2 \frac{\partial g_2}{\partial K_0}
\end{pmatrix}, \quad D = \Sigma \eta_i^2 \begin{pmatrix} 1.0 & d_i \\ d_i & d_i^2 \end{pmatrix},
\]

and the right-hand expressions are evaluated at the estimated parameters.

Our simulation considered three different error assumptions.

**Simulation 1** The observational error model where all fish are assumed to have common growth parameters, with variation due wholly to observational errors \( \varepsilon_{1i}, \varepsilon_{2i} \sim N(0,\sigma^2) \). Here, all \( \varepsilon_{3i} \) are assumed to be zero.

**Simulation 2** The variation in \( L_\text{a} \), model, where all variation in the observations are due to \( \varepsilon_{3i} \sim N(0,\sigma^2) \),
and all observational errors $\epsilon_{1i}$ and $\epsilon_{2i}$ are assumed to be zero.

**Simulation 3** Both observational errors and variation in $L_w$ are present in this model, with $\epsilon_{1i}, \epsilon_{2i}, \epsilon_{3i} \sim N(0,\sigma^2)$.

For these simulations, we assume that the true population parameters are ($L_w = 61.23, K_v = 0.296$), parameters previously estimated for female Pacific whiting (Kimura 1980). Measured in years, $t_{1i}$ and $d_i$ were uniformly and independently distributed over the interval [1, 5], assuming 365 d/yr. New values for $t_{1i}$ and $d_i$ were generated for every replication of the simulation.

Analytic standard errors of parameter estimates were estimated using nonlinear least-squares methods, and the variance estimate described above for James' method. In addition, the sample standard errors (i.e., the sample standard deviation of the replicate parameter estimates) are also provided. The reason for this is that the simulations included variation in $t_{1i}$ and $d_i$ that would not be included in the analytic estimates of standard error, and the probability that the analytic standard errors are themselves biased due to failure of assumptions. For the actual datasets, analytic standard errors were used. For simultaneously considering bias and variance, we include estimates of mean square error (MSE) calculated in the usual way: $\sum (\text{estimate} - \text{true})^2/n$.

Following a presentation of simulation results, we analyze tag-recapture data collected for sablefish Anoplopoma fimbria from the Gulf of Alaska and off the U.S. west coast, and Pacific cod Gadus macrocephalus from the eastern Bering Sea (Fig. 1). Because sablefish and Pacific cod are difficult species to directly age, their growth-curve parameters estimated from tag-recapture data are of special interest. The von Bertalanffy parameters estimated from tag-recapture data were compared with parameters estimated from length-at-age data based on direct ages (i.e., ages from directly counting annuli). For sablefish, we use length-at-age datasets based on break and burn ages (Chilton & Beamish 1982) and parameters estimated using nonlinear least-squares (Kimura 1980). For Pacific cod, we compare tag-recapture results with published von Bertalanffy parameter estimates (Thompson & Bakkala 1990).

**Results**

**Simulation results**

For the simulation results given here, the tag-recapture sample size was $n = 300$, simulations were replicated 200 times, and the normal errors ($\epsilon_{1i}, \epsilon_{2i}, \epsilon_{3i}$) were all independently distributed with $\sigma^2 = 25$. Therefore, the sample size was realistically small and the error variances were substantial. For each estimation method and parameter, simulation results (Table 1) were summarized by four entries: sample mean of the estimated parameter, mean analytic standard error, sample standard error (i.e., the standard deviation of estimated parameters), and mean square error.

The unweighted Fabens' estimate of $L_w$ is biased low in Simulation 1, biased high in Simulation 2, with biases apparently canceling each other in Simulation 3. For the weighted Fabens' estimates, the $L_w$ estimate is unbiased for Simulation 1, but biased high for Simulations 2 and 3. James' estimate of $L_w$ is unbiased in Simulation 2, and only modestly biased in Simulations 1 and 3. Biases in $L_w$ and $K_v$ estimates are in the opposite direction, as might be expected from the negative correlation between these parameter estimates.

Standard errors are uniformly smallest for the unweighted Fabens' method, in the middle for the weighted Fabens' method, and largest for James' method.

Performance as measured by mean square error was entirely dependent on the assumptions of the simulation. For Simulation 1 (i.e., observational errors) the weighted Fabens' method MSE was smallest; for Simulation 2

Simulation results using three different methods to estimate von Bertalanffy parameters ($L_\infty=61.23$, $K=0.296$) under three different error assumptions: Simulation 1 (observational error), Simulation 2 (variation in $L_\infty$), and Simulation 3 (both observational error and variability in $L_\infty$). For each estimation method and parameter, simulation results are summarized by four entries: sample mean of the estimated parameter, mean analytic standard error, sample standard error (i.e., standard deviation of estimated parameters), and mean square error.

Estimates from sablefish tag-recapture data

Sablefish is a species characterized by rapid growth at young ages followed by extremely slow growth at older ages. In tag-recapture data, it is common for sablefish to show negative growth increments (Figs. 2, 3, 5, 6). The exact reason for this apparent shrinkage is uncertain. However, Sasaki (1985) noted that shrinkage was usually reported for larger male (>60 cm) and female (>70 cm) sablefish. This suggests that such occurrences are due to the combined influence of slow growth and measurement error. Furthermore, Beamish & Chilton (1982) noted that the freezing of commercially-caught fish could cause actual shrinkage. Interestingly, Beamish & Chilton (1982) also noted that data from freshly-caught fish measured by trained biologists occasionally showed shrinkage, indicating that shrinkage can occur in the ocean environment. Considering these factors, all recoveries, including those having negative growth increments, were used in the sablefish data analyses.

Although this species is extremely difficult to age (Kimura & Lyons 1991), age-determination criteria have been validated using oxytetracycline tags (Beamish & Chilton 1982) and radioisotope methods (Kastelle 1991). Because of the difficulty of directly determining ages for sablefish, estimating growth using tag-recapture data is of particular interest.

(variability in $L_\infty$) the James’ method MSE was the smallest; for Simulation 3 (i.e., both observational error and variability in $L_\infty$) the unweighted Fabens’ method MSE was the smallest.

It is clear from these simulation results that unweighted or weighted Fabens’ estimates of von Bertalanffy parameters can be significantly biased. It is also clear that standard errors for James’ estimators tend to be larger than standard errors for the unweighted and weighted Fabens’ estimators.
Sablefish growth differs between regions, so we analyzed tag-recapture data from the Gulf of Alaska and the west coast of the United States separately (Fig. 1). Sablefish growth differs greatly by sex (Sasaki 1985), so it was necessary to estimate growth parameters for each sex.

Because the type of fishing gear used for tagging and recapture might affect the observed growth increments, we include tables of tagging and recapture gears for the usable data for all actual data sets (Table 2). Fish in the Gulf are primarily caught using longline gear, while fish off the west coast are primarily caught by trawl and pot gears.

For Gulf of Alaska sablefish, 133,558 fish were released, with 7946 recoveries between 1972 and 1990. Of these recoveries, 1340 had usable growth-increment information (Figs. 2, 3). Longline gear dominated both tag and recovery gears (Table 2).

Estimated von Bertalanffy parameters for sablefish in the Gulf of Alaska based on tag-recapture data can be compared with von Bertalanffy parameters estimated directly from length-at-age data (Table 3) from specimens collected on longline surveys in 1987 and 1989, and aged during 1990 and 1991 (Fig. 4). For this dataset the unweighted Fabens' estimates, the James' estimates, and estimates based on direct ages gave very similar parameter estimates. However, the weighted Fabens' estimates gave estimates quite different from the others.

</table>
For west coast sablefish, 52,743 fish were released, with 4220 recoveries between 1971 and 1991. Of these recoveries, 1083 had usable growth-increment information (Figs. 5,6). Pot gear was the dominant release gear, but both trawl and pot were important recovery gears (Table 2).

Estimated von Bertalanffy parameters for west coast sablefish based on tagging data can be compared with von Bertalanffy parameters estimated directly from length-at-age data (Table 4) from specimens collected in trawl and pot surveys in 1983 and 1989, and aged during 1991 and 1992 (Fig. 7). For this dataset, only James’ estimates compared well with estimates based on direct ages. If James’ estimates were not available, we could not conclude that estimates of growth parameters based on tagging were consistent with length-at-age data generated by age readers. Unexpectedly for the west coast dataset, James’ estimates of SE(L0) were smaller than for the unweighted Fabens’ estimates.

Another possible problem when analyzing growth-increment data is that the observed increments may be dependent on the tag or recovery gears that are used. Our west coast sablefish tag-recapture dataset provides an opportunity to examine whether observed growth increments may depend on the fishing gears used for tagging and recapture. From this dataset, we selected only fish with pot gear releases and trawl or pot gear recoveries. We then regressed growth increment against sex, recovery gear, size-at-release, and time at liberty. The analysis showed that fish recovered by pot gear could be expected to have growth increments 3.7 cm larger (significant α=0.0001) than fish recovered by trawl gear after the other independent variables were taken into account. Thus, release and recovery gears can be expected to affect the growth curves estimated from tag-recapture data.

Estimates from Pacific cod tag-recapture data

Pacific cod has also proved to be a very difficult species to directly age (Kimura & Lyons 1990). For eastern Bering Sea (Fig. 1) Pacific cod, 12,396 tagged fish were released, with 375 recoveries between 1982 and 1989. Of these recoveries, 284 had usable growth-increment information (Fig. 8). Bottom trawl was the only release gear, but both trawl and longline were important recovery gears (Table 2). Because of the small tag-recapture sample size available for Pacific cod, we combined male and female data into a single fit.

As with sablefish, Pacific cod tag recaptures can show negative growth increments (Fig. 8). For the complete tag-recapture dataset, unweighted and weighted Fabens’ estimates were biased when compared with estimates based on length-at-age data (Table 5). James’ estimates did not exist within a reasonable range for K0 (0.01<K0<1.0). Using recoveries with only positive growth increments allowed James’ estimates to be close to those based on length-at-age data (Table 5). After deleting only the larger negative growth increments (i.e., larger in absolute value), data with increments greater than −10 cm gave a standard error for L0 using James’ method of 53.4 cm. These results indicate that for James’ estimates, the sample size for Pacific cod was insufficient to overcome variability in the data.

Discussion

Our simulation study confirmed that James’ robust estimators for estimating von Bertalanffy parameters from tag-recapture data show little bias when variability can be described by simple observational error and/or variability in L0. In contrast, the unweighted and weighted Fabens’ estimators sometimes had...

Figure 7
von Bertalanffy growth curves for male (top) and female (bottom) sablefish off U.S. west coast, calculated from length-at-age data.

Figure 8
Length-frequency at time of release (top) and relationship between time at liberty and growth (bottom) for Pacific cod in eastern Bering Sea.

Table 5
Comparison of von Bertalanffy growth parameters for Pacific cod in eastern Bering Sea, estimated from tag-recapture data using all growth increments (n=284), only positive growth increments (n=252), and length-at-age data. Sexes were combined, and von Bertalanffy parameters estimated from length-at-age data were taken from Thompson & Bakkala (1990). NS = no solution, NA = not available.

large biases. However, the standard errors for James’
estimators tended to be larger, so in terms of mean
square error the superior estimation method depended
on the assumptions we made concerning variability.

Weighted Fabens’ estimators performed well when
error was restricted to observational error, but were
badly biased when variability in L∞ was introduced
into the simulation. In contrast, James’ estimators per­
formed well when there was no observational error
and error was due only to variability in L∞. The
unweighted Fabens’ estimators were biased when er­
er was solely observational, and biased when variabil­
ity was due solely to variability in L∞, but biases
apparently canceled when both errors were present.

It is difficult to recommend the unweighted or
weighted Fabens’ estimators because they are both sub­
ject to large biases. It seems difficult to assume biases
will cancel, or that there will be no variability in the
data due to variability in L∞.

On the other hand, the James’ estimators appeared
unbiased but tended to have larger standard errors.
Our experience with analyzing the small sample-size
dataset available for Pacific cod indicates that James’
estimators may require at least moderate sample sizes,
the required size depending on variability in the data.
If sample sizes are sufficiently large, reducing bias
can be far more important than increasing efficiency.
Therefore, it seems important that James’ estimators
be used to at least guard against possible biases. More
experience with James’ method will probably be needed
before researchers can finally decide the correct scope
of application for this new method.

In this paper we have used von Bertalanffy param­
eter estimates based on direct ages as the yardstick by
which to measure bias for the three different estimat­
ors. Of course, von Bertalanffy parameter estimates
based on length-at-age data might themselves be bi­
ased. Except for the small sample-size dataset avail­
able for Pacific cod, James’ estimators compared well
with estimates based on direct age data. Unweighted
Fabens’ estimators compared well with estimates based
on direct ages for one dataset. Weighted Fabens’ esti­
mators of L∞ appeared to be biased high for all three
datasets.

This pattern of bias suggests that the tag-recapture
data in these actual datasets contain significant amoun­
ts of variability due to variability in L∞. This is also
evidenced by the length-at-age data (see Figs. 4,7).
For the three stocks of fish studied in this paper, we
conclude that there are no inconsistencies in growth
described by direct ages and growth described by tag­
recapture data. Without James’ estimators, this con­
clusion could not be made. We feel that James’ method
represents a significant step forward, and that datasets
previously analyzed using Fabens’ method might ben­
efit by being reexamined using James’ method. How­
ever, results may be the same as Fabens’ estimates, or
quite different, depending upon the nature of variabil­
ity in the data.

Still, problems remain when evaluating growth from
tag-recapture data. McFarlane & Beamish (1990) con­
cluded that external tags could markedly affect the
growth of sablefish. We have shown that different
fishing gear types may select for slower- or faster­
growing individuals. For the west coast sablefish tag­
recapture datasets, growth increments appeared larger
for fish recovered with pot gear compared with trawl
gear. Therefore, sampling gears always play a role in
describing the growth parameters we estimate.

Acknowledgments

We thank R.A. Maller, an anonymous referee, and the
editorial staff of the journal for comments that greatly
facilitated our revision. We thank F.R. Shaw for provid­
ing access to the sablefish tag-recovery database. This
study was motivated by original insights into tag-re­
capture growth parameter estimation from I.R. James.
