# ABUNDANCE AND DISTRIBUTION OF LARVAL FISHES IN WATERS OFF OREGON, MAY-OCTOBER 1969, WITH SPECIAL EMPHASIS ON THE NORTHERN ANCHOVY, ENGRAULIS MORDAX 

Sally L. Richardson ${ }^{1}$

#### Abstract

Quantitative information on larval fishes in waters off Oregon is presented. Three hundred fifty-four samples, containing 55,049 larvae, were taken from lat. $42^{\circ} 00^{\prime}$ to $46^{\circ} 30^{\prime} \mathrm{N}$ and from the coastline to long. $129^{\circ} 30^{\prime} \mathrm{W}$ during six cruises, May to October 1969. Catches by three types of gear-bongos, meter net, and Isaacs-Kidd midwater trawl-are compared. The midwater trawl captured the greatest number of taxa and had the greatest frequency of occurrence of major taxa while overall the bongos caught the most larvae per $1,000 \mathrm{~m}^{3}$ of water filtered. Shallow tows compared with deep tows from the same stations showed small anchovy larvae were concentrated near the surface while larvae of myctophids and scorpaenids were more common in deeper waters. Species composition ( 40 taxa in 22 families from deep tows), frequency of occurrence, abundance, and dominance are discussed. Northern anchovy, Engraulis mordax; northern lampfish, Stenobrachius leucopsarus; blue lanternfish, Tarletonbeania crenularis, and Sebastes spp. were the most dominant taxa. Distributional features of species in the most important families are described. E. mordax larvae were concentrated in Columbia River plume waters from June to August.

Species composition, abundance, seasonal occurrence, and areal distribution of larval fishes in ocean waters of the northeast Pacific off Oregon are virtually unknown (Ahlstrom, 1968). Pearcy (1962) ${ }^{2}$ and LeBrasseur (1970) ${ }^{3}$ listed larval fishes from these waters collected only incidentally to major sampling goals. Waldron (1972) provided the first quantiative data on larvae off Oregon collected from 12 April to 11 May 1967. No additional comprehensive, quantitative information has been published.

From 10 May to 31 October 1969, the Department of Oceanography of Oregon State University conducted a series of cruises off Oregon to quantitatively study the chemical, physical, and biological interrelationships involved with

[^0]Manuscript accepted February 1973.
FISHERY BULLETETIN: VOL. 71, NO. 3, 1973.
two major oceanographic phenomena-the Columbia River plume and coastal upwelling. The area surveyed extended from lat. $42^{\circ} 00^{\prime}$ to $46^{\circ} 30^{\prime} \mathrm{N}$ and from the coastline to long. $129^{\circ} 30^{\prime} \mathrm{W}$.

This extensive sampling effort yielded much quantitative information on abundance and distribution of larval fishes off Oregon. Three types of gear are compared for their effectiveness in catching fish larvae. Shallow tows are compared with deep tows made at the same stations on two cruises. Species composition, frequency of occurrence, abundance, and dominance are discussed. Occurrence and distribution patterns are described for species in the most important families.

## MATERIALS AND METHODS

Six cruises were conducted at approximately monthly intervals from 10 May to 31 October 1969 in waters off Oregon. Inclusive cruise dates and stations occupied during these cruises are shown in Figure 1.

Figure 1.-Stations occupied during survey of waters off Oregon, May to October 1969.

Micronekton and zooplankton were sampled with a 6 -foot Isaacs-Kidd midwater trawl (IKMT) equipped with a $5-\mathrm{mm}$ mesh liner and a $0.571-\mathrm{mm}$ mesh cod end, paired 0.7 m (mouth diameter) bongos with $0.571-\mathrm{mm}$ mesh nets, and a $5-\mathrm{m}$ long $1.0-\mathrm{m}-$ mouth diameter net (MN) with a $0.571-\mathrm{mm}$ mesh.

The bongos were located 3 m above the bridle of the IKMT on the same tow line. Hauls were made obliquely, usually from 200 m , depth permitting, to the surface at a tow speed of 5 knots. Eight hundred meters of wire, assuming a 4:1 wire length to depth fished ratio, was let out at $50 \mathrm{~m} / \mathrm{min}$ and retrieved at $30 \mathrm{~m} / \mathrm{min}$. A usual haul required about 40 min effective towing time. Surface tows (upper $10-20 \mathrm{~m}$ ) were made horizontally at the same stations as deep ( 200 m ) oblique tows on the June and JulyAugust cruises for comparison. Three of these surface tows did not have paired samples from deep hauls. For MN hauls, the ship remained stationary as the net was lowered at $10 \mathrm{~m} / \mathrm{min}$ to 200 m on 200 m of wire, depth permitting, and hauled vertically to the surface at $30 \mathrm{~m} /$ min. Effective tow time was usually about 8 min . At depths $<400 \mathrm{~m}$ only the upper half of
the water column was sampled by the IKMT and bongos. Bongos were not used on the May or August cruises. MN samples were not always taken in conjunction with IKMT samples. All tows were made between dusk and dawn.

A flow meter was situated inside the mouth of each net to record volume of water filtered. A depth distance recorder (Pearcy and Laurs, 1966) was also used in the IKMT to record the distance travelled vs. depth.

Temperature (BT) and salinity (induction salinometer) of surface waters were determined at each station.

All biological samples were preserved at sea in $10 \%$ buffered seawater Formalin. ${ }^{4}$ Later the IKMT samples were transferred to $36 \%$ isopropyl alcohol. Fish larvae were sorted from bongo (one side only), MN (some of which had been split a varying number of times with a Folsom plankton splitter), and IKMT samples (not split). They were later identified and measured. Measurements, reported to the nearest millimeter, refer to standard length (SL $=$ snout tip to notochord tip preceding development of caudal fin, then to end of hypural plate). For convenience, the term larvae in this paper sometimes includes early juvenile stages, e.g., anchovies, scorpaenids, and osmerids.

The taxonomic listings follow the scheme of Greenwood et al. (1966). Species names correspond to those listed by the American Fisheries Society (Bailey, 1970). The following discussion is based on the deep tows of the bongos and IKMT unless indicated otherwise.

## RESULTS AND DISCUSSION

## Comparison of Gear

The three types of gear were compared for the number of taxa taken, estimates of larval abundance, and frequency of occurrence of major taxa. The IKMT samples contained the greatest number of taxa followed by the bongos and MN (Table 1). Many of the bongo and MN samples, but not IKMT samples, had been split prior to removal of fish larvae. This process

results in a loss of rare taxa in the split fraction. The IKMT was towed the longest and filtered the greatest volume of water which increased the probability of capturing rare taxa. This factor outweighed the loss of larvae by escapement through the $5-\mathrm{mm}$ mesh liner which would be expected to be great.

Bongo samples gave the largest estimate of larval abundance (individuals $/ 1,000 \mathrm{~m}^{3}$ ) for combined cruises. (Although not done in this paper, subsequent data on larval fishes will be standardized to numbers under a unit area of sea surface as encouraged by E. H. Ahlstrom.) Bongos captured a large number of anchovies on the July-August cruise which mainly accounted for the large estimate for combined cruises. MN samples gave the largest estimates of abundance for five of the six periods sampled. The bongos were towed at a speed of 5 knots which may have resulted in extrusion of small larvae. This would explain the low estimates of abundance on three of the four cruises compared with the MN which was hauled more slowly
and primarily took small larvae. The IKMT gave the smallest estimates of abundance of larval fishes for each cruise and for the combined cruises probably because of a high degree of escapement through the net by small forms.

Numbers of taxa occurring in $5 \%$ or more of the samples for each gear were: 7 for the bongos, 5 for the MN, and 19 for the IKMT (Table 2). For each gear the four taxa taken most frequently were northern anchovy, Engraulis mordax; northern lampfish, Stenobrachius leucopsarus; blue lanternfish, Tarletonbeania crenularis, and Sebastes spp. (Sebastes spp. was fifth in bongo samples preceded slightly by Promyctophum thompsoni.) However, percent frequency of occurrence of each of the four, except S. leucopsarus, varied considerably among types of gear (Table 2). Percent occurrence of E. mordax was similar in bongo and IKMT samples but much lower in MN samples. The IKMT took T. crenularis and Sebastes spp. much more often than either the bongos or the MN. The greater frequency of occurrence of

taxa in the IKMT samples is probably due to the greater volume of water filtered.

## Shallow vs. Deep Tows

Shallow tows of the IKMT and bongos made on the June and July-August cruises were compared with the standard deep tows from the same stations. Volume of water filtered was approximately the same for each shallow and deep pair. In shallow tows, positive samples (47 out of 64) yielded 20,629 fish larvae compared with 18,087 larvae in 50 out of 64 samples from deep tow pairs (Table 3). A total of 31 taxa were taken; 17 occurred in both shallow and deep samples, 3 occurred only in shallow samples, and 11 were only in deep samples (Table 4). Ninety-eight percent of all larvae were distributed in three families for shallow and deep tows:

Shallow tows:
89.4\% Engraulidae in $35.9 \%$ of all samples 5.7\% Myctophidae in $31.2 \%$ of all samples $2.9 \%$ Osmeridae in $14.1 \%$ of all samples

## Deep tows:

$73.1 \%$ Engraulidae in $31.2 \%$ of all samples
23.8\% Myctophidae in $95.3 \%$ of all samples
$1.7 \%$ Scorpaenidae in $26.6 \%$ of all samples
Deep tows consistently yielded a greater number of taxa because they sampled more completely the vertical range of larval fishes. The taxa most frequently taken ( $>20 \%$ of samples) in shallow tows were $E$. mordax, S. leucopsarus, and speckled sanddab, Citharichthys stigmaeus. In deep tows they were S. leucopsarus, E. mordax, Sebastes spp., Cyclopteridae, and T. crenu-
laris. Frequency of occurrence of E. mordax in samples was generally higher in shallow tows than in deep tows (the same in shallow and deep bongo samples from July-August). On both the June and July-August cruises the bongos took more anchovies in surface tows than in deep tows. The IKMT took no anchovy larvae in June and in July-August captured more anchovies in deep tows than in surface tows. The IKMT is more selective for larger forms because small larvae can escape through the net. Thus small anchovy larvae appear to be concentrated in surface waters, with larger larvae
occurring deeper. Myctophids, scorpaenids, bathylagids, and cyclopterids had a much higher frequency of occurrence in deep tows.

## Species Composition

Positive samples (207 out of 287) yielded 28,489 fish larvae from all deep tows (Table 1). Of the 40 taxa, 28 were identified to species and 6 to genus. Twenty-two families were represented.

Ninety-eight percent of all larvae (individuals $/ 1,000 \mathrm{~m}^{3}$ ) in combined samples were in four families:

> 68.4\% Engraulidae in $29.6 \%$ of all samples $25.3 \%$ Myctophidae in $96.9 \%$ of all samples $4.2 \%$ Scorpaenidae in $34.1 \%$ of all samples $0.4 \%$ Osmeridae in $4.2 \%$ of all samples

Other families represented in over $5 \%$ of the samples were: Pleuronectidae, $19.5 \%$ of all samples; Cyclopteridae, 15.7\%; Bathylagidae, $14.3 \%$; Bothidae, $13.6 \%$; Chauliodontidae, $9.8 \%$; and Paralepididae, $7.3 \%$.

During the sampling period, abundance of larvae per $1,000 \mathrm{~m}^{3}$ estimated from combined samples (Table 1) peaked in July-August and was lowest in October. Results from the MN indicated greatest abundance in May and June. The MN collected many small E. mordax in June and S. leucopsarus in May and June (Table 5). By the July-August cruise, larvae of these two species were still abundant, however the larger specimens were not as readily captured by the more slowly hauled MN.

## Dominance

Dominant taxa for each type of gear during each cruise were determined by a ranking system (biological index, BI) modified from Fager (1957). By this method, the most numerous species in each sample is given 5 points, the next 4, etc. Scores for each taxa are summed for all positive samples for each cruise and each type of gear and divided by the total number of samples (positive and negative) on that cruise by that gear. Both abundance and frequency of occurrence are considered in this determination.

BI values from each type of gear and all gear
combined for combined cruises indicated the same four taxa were most dominant, E. mordax, S. leucopsarus, T. crenularis, and Sebastes spp., although not necessarily in that order (Table 6). $S$. leucopsarus had a higher BI value than $E$. mordax in MN samples and combined samples. Sebastes spp. ranked above $T$. crenularis in IKMT samples. A drop in BI value, indicating a lower degree of dominance, existed between the fourth and fifth highest ranked taxa for each gear, particularly MN and IKMT, and combined gears. Only the bongos agreed with taxa shown to be in the top 11 by combined gears, although not in the same order.

Some of the discrepancy among gear types may be explained by size of organisms captured. The high BI values of osmerids; rex sole, Glyptocephalus zachirus; and Lestidium ringens in IKMT samples was in part due to the large size of most specimens which would avoid the smaller types of gear. None of these taxa was captured by the MN and generally few were taken by the bongos. Some of the higher ranked taxa from bongo and MN samples, Pacific viperfish, Chauliodus macouni, and Bathylagus ochotensis, are very slender forms which may escape readily through the IKMT net. Specimens of pinpoint lampfish, Lampanyctus regalis, taken by the MN in June were small, mostly 3 to 4 mm , and may have been extruded out of the bongos because of the fast tow speed. BI values indicate that the IKMT captured more large organisms, the MN captured more small or slender forms, and the bongos were intermediate.

The most dominant (BI) taxa in May (all gear combined) were Sebastes spp. and S. leucopsarus; in June, S. leucopsarus and T. crenularis; in July-August, E. mordax and S. leucopsarus; in August and September, S. leucopsarus, $\dot{E}$. mordax, T. crenularis; and in October, Sebastes spp. and E. mordax (Table 7). All had a $\mathrm{BI}>1$. All taxa below these had a $\mathrm{BI}<1$, usually with a considerable drop in BI value from the most dominant taxa. S. leucopsarus, T. crenularis, and Sebastes spp. consistently ranked in the top five from May through September (Table 5). E. mordax became the most dominant species in July-August and remained dominant through October.

TABLE 5.-Numbers of larvae per $1,000 \mathrm{~m}^{3}$ of total volume of water filtered in deep hauls according to type of gear and month of cruise.

## Comments on Major Families

Discussion is limited to the most important families. Numbers of larvae refer to total numbers taken during the sampling period. Comments on distribution focus on inshore-offshore aspects as no north-south differences were evident except for $E$. mordax. Trends in seasonality can be determined from Tables 2 and 5.

Engraulidae (43,191 larvae in 110 samples)
E. mordax larvae were taken first on the June cruise. At that time, larval lengths ranged from 3 to 12 mm with a median at 8 mm (Figure 2A). Some were newly hatched. Spawning probably occurred from June until August in 1969 if growth rates (to 10.2 mm in 20 days after fertilization) given by Lasker et al. (1970) are comparable for this area. Surface water temperatures were cooler $\left(14^{\circ}-17^{\circ} \mathrm{C}\right)$ than the $17.5^{\circ} \mathrm{C}$ temperature used in their experiments and would result in a longer development time. The smallest larvae collected after August were 18 mm which suggests the spawning period was limited. Larval growth throughout the study period is indicated in Figure 2. Ranges of SL overlapped considerably in July-August and August, probably because of continued spawning into August. By September spawning appeared to be over and a marked increase in median length was shown from September to October.

Ranges, medians, and median quartiles of SL of larvae differed somewhat according to gear type for each cruise (Figure 2A). Some of the apparent differences may be a result of small numbers of larvae measured. The IKMT did not catch any anchovies until July-August when larvae were larger. The MN did not catch any after August probably because the larger forms avoided the net. By October, only the IKMT took anchovies (except for one specimen taken by the bongos) which had a median length of 43 mm .

Anchovy larvae were most abundant in Columbia River plume waters in June and JulyAugust. Larvae were not taken north of the Columbia River or south of the major influence of plume waters. They were not abundant near

Figure 2.-Ranges, medians, and median quartiles of lengths of Engraulis mordax, Osmeridae, Stenobrachius leucopsarus, Tarletonbeania crenularis, and Sebastes spp. according to type of gear and cruise. Numbers of harvae measured are at the top of each bar. ( $\mathrm{B}=$ bongo, $\mathrm{MN}=$ meter net, $\mathrm{MT}=$ Isaacs-Kidd midwater trawl, All $=$ combined samples, NS $=$ not sampled.)
the coastline or offshore beyond the bounds of the plume. Their distribution showed a closer correlation with temperature than salinity. Plots of larval abundance, which ranged from $<1$ to $62 / 1,000 \mathrm{~m}^{3}, 210$ to $451 / 1,000 \mathrm{~m}^{3}$, and 14 to $252 / 1,000 \mathrm{~m}^{3}$ in positive tows in deep bongo, shallow bongo, and MN samples respectively in June, are in Figure 3. Larvae were associated with water $>14^{\circ} \mathrm{C}$ which agrees with Ahlstrom's (1959) findings off California. Plots of abundance ( 2 to $840 / 1,000 \mathrm{~m}^{3}$ and $<1$ to $4,493 /$ $1,000 \mathrm{~m}^{3}$ in deep and shallow bongo samples) for July-August (Figure 4) again show larvae concentrated in water $>14^{\circ} \mathrm{C}$. Upwelling was prevalent at that time with colder water near shore. The Columbia River plume was not clearly distinguishable although the warm waters offshore were probably a result of the plume (Pearcy and Mueller, 1969). After the July-August cruise, fewer larvae were taken and distribution was scattered throughout the area sampled.

Small anchovy larvae were concentrated in surface waters which agrees with Ahlstrom's (1959) results on vertical distribution of anchovies off California.

Figure 3.-Distribution of Engraulis mordax larvae and surface temperature, June 1969.

Figure 4.-Distribution of Engraulis mordax larvae and surface temperature, July-August 1969.

Results of meristics and blood genetics studies have indicated at least three distinct anchovy subpopulations exist off Oregon, California, and Baja California (Vrooman and Smith, 1972). The present results together with previous studies offer support for the existence of a separate stock off Oregon. Anchovy larvae were abundant in Columbia River plume waters in the upper 10 to 20 m in 1969. Waters of the Columbia River plume have a strong vertical density gradient and a shallow mixed layer depth (Owen, 1968). Anchovies spawn mostly in the upper 10 m at temperatures $>14^{\circ} \mathrm{C}$ (Ahlstrom, 1959). Adult anchovies were reported in unusually large concentrations near the coast of northern California and Oregon in 1969 (Frey, 1971). The adults were probably spawning. CalCOFI (California Cooperative Oceanic Fisheries Investigations) sampling has indicated a high abundance of anchovy larvae off southern California with a substantial drop in abundance from southern to northern California. In 1949 and 1950, anchovy larvae were found in moderate abundance off Oregon (Ahlstrom, 1968). Thus, a separate spawning stock of an-
chovies seems to exist off Oregon associated with the warm, near surface waters of the Columbia River plume. The spawning period seems to be correlated with the time when warm plume water is a dominant oceanographic feature, before the rest of the ocean surface water warms to $>14^{\circ} \mathrm{C}$. Additional sampling for eggs as well as larve with even more extensive coverage is needed to determine areal extent of spawning and extent of yearly variation caused by changing oceanographic conditions.

## Osmeridae ( 687 larvae in 21 samples)

Larvae of osmerids were collected in June, July-August, August, and October at the nearshore stations shown in Figure 5. The nearshore area was heavily sampled on the JulyAugust cruise, perhaps explaining why few or no specimens were taken on other cruises. Similarly, no samples were taken near shore south of Newport (Figure 1). Distribution appears to be restricted to near shore when upwelling was prominent.

All specimens have not yet been identified to

FIGure 5.-Distribution of osmerids collected from June to October 1969.
species, although some are known to be Thaleichthys pacificus. The trend in growth in Figure 2B might indicate all the larvae were products of one major spawning and therefore one species.

Mycthophidae (8,694 larvae in 152 samples)
Larvae of S. leucopsarus ( 7,683 specimens) were taken from May to September in moderate numbers. Capture of $3-\mathrm{mm}$ individuals in May (Figure 2C) indicated spawning may have occurred recently, although early growth rates have not yet been established. The occurrence of $4-\mathrm{mm}$ larvae as late as July-August appears to extend the spawning period off Oregon beyond the December to March range estimated by Smoker and Pearcy (1970). The smallest larvae taken in September were 8 mm . No larvae were taken in October which supports the idea that $S$. leucopsarus does not spawn throughout the year off Oregon.

The IKMT generally captured larger larvae than the bongos or MN (Figure 2C). An increase in median length of larvae occurred from May through August. Individuals about to undergo metamorphosis, which occurs around 18 mm (Smoker and Pearcy, 1970), were taken from July-August to September. By October, all larvae apparently had begun the process of metamorphosis, which takes place at depths greater than we sampled (Fast, 1960).

Larvae of $S$. leucopsarus were more abundant west of long. $124^{\circ} 30^{\prime} \mathrm{W}$ (about 20 nautical miles off Newport, Oreg.) than closer to shore (Table 8) although a few specimens did occur in nearshore samples. North-south distribution was scattered. Larvae were never taken around the mouth of the Columbia River where lower salinity water fans out into the ocean. Larvae were more frequently taken in deep ( 200 m ) tows than in shallow tows (Table 4) during the June and July-August cruises.

Larvae of T. crenularis ( 714 specimens) were collected on all cruises. Larval lengths ranged from $5-7 \mathrm{~mm}$ to $19-20 \mathrm{~mm}$ on each cruise from May to September (Figure 2D). From these data, $T$. crenularis appears to spawn at least throughout the period sampled, although collection of only one specimen in October cannot be explained.

Table 8.-Numbers of individuals $/ 1,000 \mathrm{~m}^{3}$ of water filtered in deep hauls of Stenobrachius leucopsarus and Tarletonbeania crenularis taken east (near shore) and west (offshore) of long. $124^{\circ} 30^{\prime} \mathrm{W}$.

|  | Oct. | 0 | 0.05 | 0 | 0 | 0 | 0 |

Distribution of T. crenularis larvae was more predominantly offshore than that of S. leucopsarus (Table 8). In August, two specimens each were collected with the IKMT and MN at long. $124^{\circ} 24.5^{\prime} \mathrm{W}$. No additional T. crenularis were found closer to shore than long. $124^{\circ} 30^{\prime} \mathrm{W}$. Distribution was scattered from north to south within the area sampled. During the June and July-August cruises, capture of $T$. crenularis larvae was almost entirely restricted to deep tows (Table 4.)

Other myctophids were captured in smaller numbers. Lampanyctus regalis ( 151 specimens) ranged from 3 to 19 mm in length and occurred mainly west of long. $125^{\circ} \mathrm{W}$; only one specimen was taken nearer shore. Six L. ritteri, all 5 mm , were taken in two samples west of long. $127^{\circ} 30^{\prime} \mathrm{W}$ in June. Protomyctophum thompsoni ( 117 specimens, $6-20 \mathrm{~mm}$ ) occurred somewhat closer to shore than L. regalis, with a moderate number between long. $124^{\circ} 30^{\prime} \mathrm{W}$ and $125^{\circ} \mathrm{W}$. None was found closer to shore than long. $124^{\circ} 30^{\prime} \mathrm{W}$. The distribution of flashlightfish, $P$. crockeri, ( 11 specimens, $6-20 \mathrm{~mm}$ ) was similar to that of P. thompsoni. All 12 California headlightfish, Diaphus theta, $(8-13 \mathrm{~mm})$ were taken west of long. $125^{\circ} 30^{\prime} \mathrm{W}$.

Scorpaenidae ( $\mathbf{1 , 2 0 5}$ larvae in 102 samples)
Sebastes spp. (1,189 specimens) were captured throughout the sampling period. Individual species were not identified so interpretation
of data is limited. In May and June products of an earlier spawning were captured (individuals $40-55 \mathrm{~mm}$ ) along with newly hatched ( 4 mm ) larvae (Figure 2E). Growth of the smaller larvae can be observed from June to October in Figure 2E. Distribution of Sebastes spp. larvae was scattered throughout the area studied with no discernible pattern.

Larvae of Sebastolobus spp. (16 specimens, $10-40 \mathrm{~mm}$ ) exhibited a scattered distribution similar to that of Sebastes spp.

Bothidae (93 larvae, 48 samples)
Pacific sanddab, Citharichthys sordidus, (25 specimens, $8-45 \mathrm{~mm}$ ) occurred from long. $124^{\circ} 30^{\prime} \mathrm{W}$ to farther offshore. Distribution of C. stigmaeus ( 68 specimens, $17-44 \mathrm{~mm}$ ) was concentrated closer to shore than that of $C$. sordidus, although some specimens were taken west of long. $126^{\circ} \mathrm{W}$.

## Pleuronectidae (123 larvae in 52 samples)

Four petrale sole, Eopsetta jordani, (13-21 mm ) were collected in May: one off Tillamook Head at long. $125^{\circ} \mathrm{W}$, one off Newport at long. $125^{\circ} \mathrm{W}$, and two off Cape Arago-one at long. $125^{\circ} \mathrm{W}$ and the other at long. $126^{\circ} \mathrm{W}$. Glyptocephalus zachirus ( 31 specimens, $22-89 \mathrm{~mm}$ ) occurred throughout the sampling period from near shore to far offshore in no discernible pattern. All 33 butter sole, Isopsetta isolepis,
(12-22 mm) were captured east of long. $125^{\circ} \mathrm{W}$. Most larvae were close to shore. Slender sole, Lyopsetta exilis, ( 21 specimens, $10-23 \mathrm{~mm}$ ) occurred east of long. $125^{\circ} 30^{\prime} \mathrm{W}$, but were not concentrated as close to shore as I. isolepis. Dover sole, Microstomus pacificus, ( 10 specimens, $12-61 \mathrm{~mm}$ ) were all collected west of long. $125^{\circ} \mathrm{W}$. The six English sole, Parophrys vetulus, ( $18-22 \mathrm{~mm}$ ) taken in May occurred off Newport (2) and Cape Arago (4) between the coast and long. $125^{\circ} \mathrm{W}$. Sand sole, Psettichthys melanostictus, ( 18 specimens, $15-26 \mathrm{~mm}$ ) also occurred mainly between the coast and long. $125^{\circ} \mathrm{W}$; two of the specimens were taken at long. $125^{\circ} 30^{\prime} \mathrm{W}$.

## ACKNOWLEDGMENTS

I thank Sharon Myers for her help with identification of fish larvae and Michael Richardson and William G. Pearcy for their helpful comments and review of the manuscript. This research was supported in part by NOAA (maintained by the U.S. Department of Commerce) Institutional Sea Grant 2-35187.
