# INTERACTION OF FOOD LEVEL AND EXPLOITATION IN EXPERIMENTAL FISH POPULATIONS 

By Ralph P. Silliman, Fishery Biologist, Bureau of Commercial Fisheries Biological Laboratory, Seattle, Wash. 98102

#### Abstract

Nine populations of guppies (Lebistes reticulatus) were established in separate aquariums. Food supply was constant for groups of three populations in ratios of $0.5,1.0$, and 1.5 to a "standard" diet. Temperature, light, and space were constant and the same for all populations. After 28 weeks, populations had reached near-asymptotic levels, and mean numbers and weights for each group of three were in the same rank as their food levels.

Twenty-five percent, 33 percent, and 50 percent of the fish were removed per 3-week brood interval for each food-level group of three populations, thus providing nine combinations. Continuation of exploitation at these rates led to relatively stable yields during weeks 59 to 72, after initial declines due to readjustment of populations. Yield curves for each food level revealed relation of yield to exploitation rate and biomass to be independent of amount of food consumed. Maximum yields occurred near the 0.33 ( 33 percent) exploitation rate for all food levels and represented about 25 percent of the food consumed. Results suggest that if commercially fished populations behave as the experimental ones did, management strategies may be applied independently of amount of food organisms available.

The purposes of laboratory fish-population experiments and their relation to other work in fishery dynamics have been set forth rather fully by Silliman (194S) and Silliman and Gutsell (1958). Briefly, the purposes are to provide experimental measurement of the effect of expluitation on stocks of fish, under as fully controlled environmental conditions as possible. The above authors also pointed out the advantages of the guppy (Lebistes reticulatus) as an experimental animal: rapid growth and reproductive rates, small size, and hardiness.

Food supply and exploitation rate must be among the most important factors that determine biomass and yield in exploited fish populations. The response of populations to exploitation is well known, as set forth in such works as Beverton and Holt (1957). The importance of food supply, although not as fully documented, is well recognized. For example, Zheltenkova (1961) adduced data indicating that a decreased supply of food reduced the rate of growth and catches of bream

[^0]in the Sea of Azov. She also reported a number of qualitative examples in another work (1958) that, although lacking numerical estimates of food amounts, tended to support the thesis that food supply is important in determining yield and rate of growth of several fishes in the U.S.S.R. These examples indicate not only the importance of food level at any given time but also the importance ' of the great fluctuations in this level that occur from one time to another.

Quantitative support for the idea that fluctuations in food supply would modify fluctuations in fish stocks resulting from other causes was provided early by Jensen (1928). His data on measured amounts of bottom food in certain Danish waters in the fall were significantly correlated with catches of plaice.

Because yield is related to both food supply and rate of exploitation, the interaction of these two is of obvious interest to the fishery manager. Might it be possible, for instance, to harvest a greater percentage of the stock when food supply and abundance are high than when they are low? The experiments described in this report were
carried out to throw light on this and similar questions, such as precisely how yields are related to exploitation at each food level. Answers were sought by investigating the effects at controlled exploitation and food level on population biomass and yield.

## PLAN OF THE EXPERIMENT

Experimental tanks provided for three food levels and three rates of exploitation, a total of nine combinations. Because of limited facilities and personnel, replications were not made. The experience of Silliman and Gutsell (1958) helped to determine the specific food levels and exploitation rates to use. In each test the levels were chosen to bracket the ones that had provided the greatest yield in the previous experiments. Maximum yield for those experiments occurred when the populations were fed a standard diet and when 25 to 50 percent of the fishable stock was removed per 3 -week period (the average interval between broods of a female guppy).

For the experiments reported here, food levels of $0.5,1.0$, and 1.5 times the "standard" diet were arbitrarily selected. An arbitrary selection of exploitation rates at $0.25,0.33$, and 0.50 per 3 -week period was also made. The resulting nine combinations were assigned by lot to a row of nine experimental tanks, as follows: Tank $A$, diet 1.0 , exploitation rate $0.25 ; \mathrm{B}, 0.5,0.25 ; \mathrm{C}$, $1.5,0.50 ; \mathrm{D}, 1.0,0.50 ; \mathrm{E}, 1.5,0.25 ; \mathrm{F}, 0.5,0.33$; G, $1.0,0.33 ; \mathrm{H}, 0.5,0.50 ; \mathrm{I}, 1.5,0.33$.

The plan of the experiment was simple: To start a population of guppies in each tank and allow all to grow until asymptotic size or a close approach to it had been attained. The populations were then exploited at the chosen rates, and this was continued until the yield from each tank became reasonably stable.

## MATERIALS AND METHODS

The experiments were conducted from January 30, 1964, through June 17, 1965, at the former Biological Laboratory, Bureau of Commercial Fisheries, Washington, D.C.

## FISH TANKS AND EQUIPMENT

Conventional glass-walled aquariums were used as experimental tanks (fig. 1). The water surface in each was 44 by 24 cm .; and the depth, 19 cm . (volume, 20 l.). Each was provided with a cotton-
charcoal filter (inside the tank) and an airstone. A pair of small pumps supplied air for both of these fixtures.

The available room illumination was used as a light source. It consisted of two banks of eight 40 -watt fluorescent lamps (fig. 1). (Evidence to be presented later in the section "Changes During Exploitation" will support the assumption that differences in amounts of light received by different populations did not confound the interpretation of the experimental results.) All windows were covered, and lights were controlled by a time switch to be on each day from 6 a.m. to 6 p.m.
Refuges for the young fish were provided by fences placed in the left "front" (facing row of tanks with $A$ to $I$ from left to right as in fig. 1) corners of all tanks. Each fence consisted of glass rods supported by plastic rails. The rods were 21 cm . long and were placed vertically to form a fence 15 cm . long. The center of each glass rod ( 3 mm . in diameter) was 4.5 mm . from the center of the next rod, leaving spaces of 1.5 mm . between rods for the passage of the young fish. Fences were placed in tanks so as to enclose a $45^{\circ}$ right triangular space in the corner of each.

A grader for separation of "fry" from "immature" sizes of fish consisted of a plastic box 20 cm . long with ends 10 cm . square. This box was open at the top, and the bottom was composed of plastic rods, 3 mm . in diameter, placed parallel to the longer axis of the box. Because centers of the rods were 5 mm . apart, $2-\mathrm{mm}$. spaces were left for grading the fish. All fish which would pass through the grader were classified as "fry"; immature fish which would not were classified as "immature."

## EXPERIMENTAL DIET AND PROCEDURES

The diet I used was a standard one developed during previous experiments (Silliman and Gutsell, 195S). Food consisted of medium-grade dry tropical fish food, frozen Daphnia, and newly hatched Artemia nauplii. The dry food was a commercial product containing dried mosquito larvae, dried flies, dried Daphnia, fish-liver meal, beef meal, shrimp meal, salmon-egg meal, wheatgerm meal, fish-roe meal, clam meal, fish-bone meal, dried egg yolk, whole whent menl, dehydrated kelp, dehydrated alfalfa-leaf meal, dehy-

Figure 1.-General arrangement of tanks and orientation with respect to light fixtures. Door to room was located heyond end of light fixture in upper right corner, and was not visible to fish in tanks.
drated carrot, dehydrated lettuce, dehydrated spinach, and dehydrated water cress.

The following analysis was supplied by the maker:

Artemia nauplii were produced by placing the dry eggs in 750 ml . of salt water (one level tablespoonful per 750 ml .) and incubating them 2 days at about $24^{\circ} \mathrm{C}$. Food was supplied to tanks according to the schedule in table 1 . All of the daily food allotment was placed in the tanks at one time. During the early part of the experiment some food fell to the bottom of the tanks uneaten; it was siphoned out before the following day's feeding. When the populations had grown to preexploitation sizes, all food was consumed.

1 This represents weight of eggs hatched. Actual weight of nauplii produced, for the "standard" diet was 0.105 mg . (Silliman and Qutseli, 1958) The determination was made by producing duplicate hatches of 0.4 g . of fgus; these hatehes were then dripd, weighed, and the average weight deter mined. No data were available to adjust for day-to-day variations in liatching success. The weight of nauplii revresented such a small prit of the total diet (about 1 in of 1 percent) that variations would not significantly affect total
food available.

The nine populations were started on January 30,1964 . (A list of dates for the numbered weeks of each experiment is given in table 2.) Stocks were from previously established aquariums and consisted of 432 guppies. I segregated the fish into males, females, and "juveniles," the latter including the categories "fry" and "immature" as defined above. All males were placed in a single container and then put into the nine tanks from $A$ to $I$ in succession, one fish at a time. I repeated this process until seven males were in each tank. I used a like process to put eight females in each tank. Similarly, 33 juveniles were placed in each tank, but they were introduced in groups of $10,10,10$, and 3. Thus, each tank
contained 48 fish- 7 males, 8 females, and 33 juveniles-chosen in a consistent manner from established aquarium stocks.

Populations were fished (exploited) at 3 -week intervals, the approximate time between broods. ${ }^{1}$ These rates bracketed the rate previously found to produce maximum yield (Silliman and Gutsell, 1958 ), which was about 0.33 per 3 -week period. The "bracketing" rates were 0.25 and 0.50 per 3 -week period. Fishing was done by removing each nth fish for fishing rate $\frac{1}{n}$ and was applied only to the "immature" and "adult" fish, excluding the "fry." "Adults" included all fish whose sex could be determined by external inspection; and "immatures", all others except the "fry" that passed through the grader described above.

Procedures were deseribed in more detail by Silliman and Gutsell (195s), who also reported the technique of weekly counting and weighing the fish. This essentially consisted of counting fish individually and placing them on a strainer. From the strainer fish were transferred to a previously weighed container of water on a balance.

[^1]Total weight of fish, eontainer, and water was determined, and the fish weight ubtained by subtraction.

## ENVIRONMENTAL CONDITIONS

Although temperature was controlled as closely as possible, there were some variations. These were examined in relation to possible effects on growth or survival. Oxygen determinations were also made, to ascertain if the levels were within those considered adequate for warm-water fishes.

## TEMPERATURE

Room air temperature was controlled by a thermostatically regulated window heat pump, which could either heat or cool. Water temperature about 8 cm . below the surface of tanks $A$, E , and I (fig. 1) was recorded daily at about S a.m., noon, and 4 p.m. (Only one reading per day was taken on weekends.) 'The means indicated reasonably stable temperatires (table 3). No 30-day mean deviated more than $0.7^{\circ} \mathrm{C}$. from the grand mean. The means for all three times of day gave some indication that tank $A$ weraged higher than the others, but the greatest excess of A over either E or I was $0.5^{\circ}$ C. Likewise, the means for all three tanks. indicated that the 4 p.m. reading tended to be lower than the others, but again the greatest departure was $0.5^{\circ} \mathrm{C}$. The means of "All 3 by All 3 " revealed no consistent trend in temperatures during the experiment. The total range of individual temperature readings during the entire experiment was from $21.1^{\circ}$ to $27.2^{\circ} \mathrm{C}$.

[^2]The rather small deriations just recorded suggest that temperature was fairly well controlled. Any effects on growth or survival must have been slight, and no further analysis of temperatures seems justified.

## OXYGEN CONCENTRATION

Oxygen determinations were made for each tank during March 29 to April 14, 1965. Readings ranged from 4.54 to 5.5 S p.p.m., all within or above the 3 to 5 p.p.m. that Lewis (1963) eonsidered adequate for warm-water fishes.

Ozone was used in the tanks to control algae during weeks $56-72$. This was supplied by a "Sander Ozonizer" ${ }^{2}$ at the rate of 5 mg . per hour. Except for occasional treatments of individual tanks, the 5 mg . per hour was delivered to the main air supply, thus being divided among the nine tanks. Previous tests with fish not included in the experiments produced no mortalities when the entire 5 mg . per hour was supplied to a single $20-\mathrm{l}$. tank. No relation was noted between growth of algae and food supply or amount of light.

## POPULATION CHANGES

For purposes of analysis, the experiment was arbitrarily divided into periods before (weeks $0-28$ ), and after (weeks 29-72) exploitation began. Changes during the first period reflected increases in number and biomass resulting from reproduction and growth. Exploitation was responsible for the major changes in the second period, resulting in initial declines followed by relative stability in both population size and yield.

## INITIAL GROWTH OF POPULATIONS

The stocks entered a period of growth in numbers and weight, each stock influenced by the amount of food supplied. Mean numbers and weights each week for the group of three tanks at ench food level (tables 4 and 5 , and fig. 2) clearly bring out the influence of food supply on growth. Total weights of the stocks were in the same rank as, but not exactly proportional to, amounts of food supplied. During weeks 21 to 28 , mean weights for diet levels $0.5,1.0$, and 1.5 were $14.5,26.0$, and 36.6 , respectively. These

[^3]

Figure 2.-Initial growth of populations. Data are means for the threc populations at each diet level.
were in ratios $1.00: 1.79: 2.52$ as compared with the $1: 2: 3$ ratios of the diet levels.

A rerage numbers of fish fell even farther from the ratios of the diet levels than did the average weights. For weeks 21 to 28 they were 110, 145, and 149 in ratios $1.00: 1.32: 1.35$. Comparison of these ratios with those for average weights indicated that the individual fish averaged larger at the higher diet levels. Weights of individual fish a veraged $0.132,0.179$, and 0.246 g ., respectively, in populations at diet levels $0.5,1.0$, and 1.5 .

These results indicate that the greater biomass at the higher diet levels than at the lowest level was caused by both better survival and more rapid growth of individuals. Growth was the more important factor. The results indicate also some-
what less efficient food use at the higher diet levels than at the lowest, in the sense of the amount of biomass supported by a given amount of food. Thus, the 2.85 g . of food consumed per week (totals for Daphnia and dry food from table 1, plus 6 times $1 / 2$ of 0.000125 g . for Artemia), at the 0.5 diet level supported a biomass of 14.5 g ., or 5.1 g . per gram of weekly consumption, whereas at the 1.5 diet level the comparable figures are 8.55 g ., 36.6 g ., and 4.3 g . This loss of efficiency may have been the result of crowding the larger biomass at the higher diet levels into the same amount of space as occupied by the biomass at the lowest diet level. Alternatively, it is possible that such efficiency may simply be a declining function of size in stabilized populations.

## GHANGES DURING EXPLOITATION

It was desired to have the populations as stable as possible before the start of exploitation. Degree of stability was examined by studying the distribution of the individual populations with respect to the categories "fry," "immature," and "adult." For the 3 weeks immediately before the start of exploitation at each diet level, compositions according to these categories revealed fairly consistent patterns for the 0.5 and 1.0 levels (figs. 3 and 4), both between weeks and between

Figure 3.-Composition according to categories "fry," "immature," and "ardult'" (defined in section "Expcrimental diet and procedures') of populations at the 0. is diel level, immediately before exploitation.
populations. (Weeks of removal were staggered to facilitate the laboratory routine. Thus, exploitation at the 0.5 level began a week after that at the 1.0 level.) The compositions are characteristic of mature populations at or near the asymptotic level-mostly adults that are rather stable in number and much smaller and somewhat more fluctuating numbers of juveniles.

Characteristics of the compositions were similar at the 1.5 level (fig. 5) except for the lack of consistency between populations. (Exploitation was delayed 4 weeks in the hope that this inconsistency might disappear.) Here the differences are marked

Figune 4.-Composition according to categories 'fry," "immature," and "adult" (defined in section "Experimental diet and procedures') of populations at the 1.1) dict level, immediately before exploitation.
both in total number (as between $\mathbf{C}$ and $\mathbf{E}$ in week 34) and in percentage composition (as between C and I in week 32). These differences are surprising among populations held for more than 30 weeks under conditions of food supply, temperature, light, and space as nearly identical as possible. No ready explanation could be found among other conditions of the environment or among procedures of handling the fish. Probably genetic differences were not averaged out among the rather small numbers of adults (15) in the initial populations, in spite of the method of selection (section, "Initial growth of populations"). The differences may also have resulted from variations in gravidity among the eight adult females in each initial population. Support for some explanation related to the initial populations is found in the fact that C exceeded E and I in number and weight almost, from the start of the experiment (weeks 2 to 28 , table 3; weeks 5 to 20 and 22 to 28 , table 4).

The differences among populations at the 1.5 diet level persisted, even though the start of exploitation was delayed 4 weeks beyond that for

Figune in.-Composition aceording to categories "fry," "immature," and "adult" (detined in seetion "Experimental diot and procedures') of populations att the 1.5 diet level, immediately before exploitation.
the other six populations. I decided to proceed with exploitation of the 1.5 level group because of the substantial amount of time and effort already invested and the desire to have yields comparable with those for the other populations. This decision was supported by the fact that compositions were fairly stable within populations (fig. 5) even though discrepant between them.

Response of the populations to exploitation is indicated by the mean numbers and weights for each diet level (tables 6 to 9 and fig. 6). The saw-tooth pattern of reduction by removals and subsequent recovery is characteristic. As pointed out by Silliman and Gutsell (1958), this kind of variation reflects the resilience of natural populations as long as exploitation rates are not high enough to cause extinction.

As was also mentioned by Silliman and Gutsell, population weights are more stable than population numbers, since the latter are affected more by entrance and mortality of broods of fry. The weights reveal the typical decline in population size after the inception of explcitation, followed by near stability during the final weeks of the experiment. Although populations at all three diet levels decreased in biomass under exploitation, they maintained the preexploitation rank, which was the same as that of the diet levels.

Figure 6.-Response of populations to exploitation. Data are means for each diet level.

Table 6.-Weekly numbers and food-level means for each tank during period of exploitation; postremoval numbers for removal weeks were obtained by subtracting numbers removed (table 7); exploitation rates are indicated in parentheses. Exploitation was starled week 29 for 1.0 diet, week 30 for 0.5 diet, and week 34 for 1.5 diet

## YIELDS

Removals during the period of exploitation were comparable to the catches of commercial fisheries and provided information on stabilized yields. Data were analyzed both to determine when relative stability began and to measure the relation of yield to amount of food consumed.

## COMPARATIVE YIELDS

Yields as well as population sizes were more stable in weights than in numbers; therefore, yields were studied in terms of weight. The course of yield for each population during the exploitation period (table 9 and fig. 7) included an initial period of decline as the populations adjusted themselves to removals. This decrease was followed by a period of relative stability beginning about week 49.

Even within the relatively stable period, yields showed considerable irregularity. This phenomenon resulted from variations in the response of
the populations to exploitation and from deviations of the percentages removed from the exact nominal exploitation rates. The latter deviations occurred because the removal rates were applied on the basis of numbers of fish rather than weights. Some of this random variability is averaged out in means of yields for three 14 - or 15 -week subperiods covering the entire period of exploitation (table 9 and fig. 8). These means again reflect the initial period of decline, followed by more stable yields.
The final period, including weeks 59 to 72, was one of fairly stable yield (fig. 7). Mean yields for this period (fig. 8) ranked the same according to exploitation rate for the 1.0 and 1.5 diets. Yields at the 0.5 diet were nearly identical. The period including weeks 59 to 72 fairly well fulfilled the planned objective of "a reasonably stable yield" (section, "Plan of the Experiment"), and data from it were used in the study of relation between food level and exploitation rates. Results from this period had the additional advantage of being

Figure 7.-Yield per three weeks of each population during period of exploitation.

Figure 8.-Mean yields for three 14- or 15 -week periods. Location of vertical lines along horizontal scale indicates center of each period.
free from the irregularities in removals and mortalities that occurred at the 1.5 diet level during weeks 37 to 57 (table 7, footnotes).

## RELATION BETWEEN YIELD AND FOOD LEVEL

Data in the preceding section showed that yields at the 1.0 and 1.5 diets were related to exploitation rate, but that no such relation was detectable at the 0.5 diet. The a vailable data may now be brought together in an attempt to answer such questions as that posed in the introduction: "Might it be possible, for instance, to harvest a greater percentage of the stock when food supply and abundance are high than when they are low?" It is instructive here to relate the yields to the average total weight or biomass of the populations (table 10). Because the populations were allowed to reach asymptotic size or a close approach to it, an additional point for each yieldbiomass curve is available-that at zero rate of exploitation. If small deviations are charged to random variability, the appropriate curves (fig. 9) reveal a regular relation among exploitation rate, biomass, and yield at each diet level (curves fitted by inspection).

The curves suggested that the relation of yield to exploitation rate tends to be independent of diet level. Absolute yields were obviously dependent on amount of food available, but the greatest yield at each diet level occurred at or

Table 7.-Numbers remoned (yields) for each diet and exploitation rate: exploitation rates are indicated in parentheses

${ }^{1}$ Removals omitted because of sucidental mortalities in week 3 .
a Removals by error a added to week 43 removals in subsequent treatment.
${ }^{3}$ Ineludes aceidental mortelity.
${ }_{3}$ Omitted berause oferroneous removals in week 43.
3 Accidental mortality considered to repliace removals duc in week $5 S$.

Figure 9.-Curves indicating relation of yicld per 3-week brood interval to biomass and exploitation rate (indicated percentages) at each diet level. Points indicated for 0 percent exploitation rate are average population levels for the 3 weeks immediately before exploitation.
near the 0.33 exploitation rate (assuming that the different exploitation-yield relation at the 0.5 diet was due to random variation rather than a real difference in the relation). If the apparent independence of the exploitation-yield relation from food level reflects what happens in commer cially fished populations, the finding is significant to fishery administration. Such independence would mean that the same management strategy might be applied when food organisms are scarce as when they are abundant.

From the viewpoint of the commercial fisherman, an exploited population is a machine for converting aquatic food to marketable fish flesh. It is of interest to see how efficiently our model of the machine operated at each food level. Maximn. of the yield curves (fig. 9) indicate yields per 3 weeks of about $\dot{2} .4,3.9$, and 5.8 g . at the $0.5,1.0$,

Table 8.-Weckly weights and food-level means for cach lank during period of exploilation; poslremoval weights for removal weeks were oblained by sultracting weights removed (table 9); exploitalion rates are indicaled in parentheses. Exploitalion was starled week: 29 for 1.0 diet, week 30 for 0.5 diet and week: 34 for 1.5 diet

${ }^{1}$ Aberrant datum discarded.
and 1.5 diet levels, respectively. Amounts of food consumed at these levels were $8.55,17.10$, and 25.65 g . per 3 weels (sum of weekly totals for Daphnia and dry :ood plus $6[0.000125 \times$ diet ratio] for Artemia, all multiplied by 3, table 1); thus, conversion: efficiencies were $0.28,0.23$, and 0.23 . Again, the small difference at the 0.5 diet level probably is not significant. For practical purposes the conversions ati all three diet levels are identicul and are close to the 0.20 reported by Silliman and Gutsell (195S).

I conclude that efficiency of food conversion, as well as relation between exploitation rate and yield, is independent of amount of food available for the laboratory populations within the range of observation. Management strategies for commercially fished populaiions that behave in this manner can be applied with the expectation of the same conversion efficiency regardless of the abundance of a vailable food organisms.

This finding seems to be contrary to that re-
ported under "Initial Growth of Populations." It is noteworthy, however, that the lesser efficiency at the two higher diet levels, mentioned there, vccurred when the populations were stabilized at near asymptotic levels. Composition of such stabilized populations is different from that of exploited populations, and the growth reactions could well be different also.

The relation of food conversion efficiency to average size of individual fish can be examined by comparing the average weights with the food conversions for each of the nine populations during the expluitation period (weeks 59-72, data from tables 10 and 6 , plus food amounts quoted above). L. M. Dickie (personal communication) has pointed out to me that if conversion efficiency be plotted as a regression on averuge body weight, there is a significant negative correlation (line is $\mathrm{E}=0.317-0.667 \mathrm{~W}$, where E is conversion effiaiency as above, $W$ is average body weight, and $\mathrm{r}=-0.90$ and $\mathrm{P}<0.01$ ). This determination sup-

1 Taken as average of the weights for the three populations during the 3 weeks immediately preceding exploitation. Weeks were as follows: 0.5 diet. $28-30 ; 1.0$ diet, $27-29 ; 1.5$ diet, 32-34. Data from tables 5 and 8 .
${ }^{2}$ Data from table 8.
${ }^{3}$ Data from table 9.
ports the contention (Paloheimo and Dickie, 1965) that . . . "within a life-history stanza a given food abundance leads to a higher production of replaceable fish flesh if the producing population consists of the smaller more efficient fish than if it consists of the larger fish." He further pointed out that this regression line might be the population
counterpart of the "K-curve" which Paloheim" and Dickie developed for individual fish

$$
\left(\mathrm{K}_{1}=\frac{\Delta \mathrm{W}}{\mathbf{R} \Delta t}=\mathrm{e}^{-\mathrm{a}-\mathrm{bR}},\right.
$$

where $W$ is body weight, $R$ is rations, and a and b are empirical constants).

The fact that the "K-curve" is an exponential relation, whereas the guppy relation is linear, may stem from the wide range of sizes of individual fish in the guppy populations (about $10-40 \mathrm{~mm}$. in length). It may also result from the chief method of population control among guppies-cannibalism. This behavior causes the food of the larger fish to pass through two or more trophic levels, with a consequent lowering of conversion efficiency. Obviously, such an effect would be the mare pronounced the larger the average size of individual fish in the population, as long as smaller fish are present for prey, as was true for all populations during the exploitation period.

## SUMMARY

1. Nine experimental populations of the guppy, Lebistes reticulatus, were established in $20-1$. aquariums.
2. Groups of three populations selected by lot were fed at rates $0.5,1.0$, and 1.5 times the "standard" diet.
3. Amount of food, temperature, space, and light were held constant during the course of the experiment.
4. During weeks 21 to 28 of the experiment, mean weights of populations at the $0.5,1.0$, and 1.5 diet levels were $14.5,26.0$, and 36.6 g ., respectively; mean numbers of fish were 110,145 , and 149.
5. The greater mass of the populations at the higher diet levels than at the lowest reflected faster growth more than better survival.
6. Exploitation of the populations in each diet level group of three was applied at rates of 0.25 , 0.33 , and 0.50 per 3 -week reproductive period. There were, thus, nine diet-exploitation combinations. Exploitation was started during weeks 29 to 34 , when the composition of the populations was reasonably stable, and continued to the end of the experiment during weeks 70 to 72 .
7. Populations responded to exploitation with an initial drop in numbers and weight, followed by near stability in weight at new lower levels (numbers were less stable, owing to entrance and mortality [through cannibalism or otherwise] of broods of new-born fish).
S. Yields in weight during the final 14 weeks of the experiment were reasonably stable and were used in the study of the interaction between food level and exploitation.
8. Curves of yield as related to biomass and exploitation rate at each diet level showed that the relation of yield to exploitation rate was independent of diet level.
9. Yields were maximum near the 0.33 exploitation rate for all diet levels, and absolute amounts were $2.4,3.9$, and 5.5 g . per 3 -week period for the $0.5,1.0$, and 1.5 diets, respectively.
10. The maximum yields represented conversion of about 25 percent of the food consumed, for all three diet levels.
11. Results suggest that, to the extent that commercially fished populations behave similarly to the laboratory populations, management strat-
egies may be applied regardless of abundance of food organisms.

## ACKNOWLEDGMENTS

Most of the initial stock of guppies was donated from an aquarium maintained by Julius Rockwell. Jr. Part of the stock remained from experiments performed by Nancy Maynard. John Pricci, William Frazier, and Josephine Dickens fed and maintained the fish (all five of these people were members of the Bureau of Commercial Fisheries). L. M. Dickie and his staff of the Fisheries Research Board of Canada furnished useful suggestions which were followed in revising the manuseript.
